The function of the β -subunit is not clearly known, but this subunit appears to be required for proper assembly and targeting of the catalytic subunit. Perhaps the β -subunit has a function in maintaining the structure of the α -subunit to enable effective binding of K^+ ion to the outside face of the α -subunit. The H^+,K^+ -ATPase β -subunit has the sequence Phe–Arg–His–Tyr in its cytoplasmic domain. This tyrosine has been shown to be important for the retrieval of the H^+,K^+ -ATPase from the apical membrane of the parietal cells and to ensure its return to the tubulovesicular compartment in order to terminate the process of acid secretion. The participation of a tyrosine-based signal in the retrieval of the H^+,K^+ -ATPase suggests that this process involves interactions with adaptins and is mediated by clathrin-coated pit formation. In knockout mice, deficient in the H^+,K^+ -ATPase β -subunit, cells that express the H^+,K^+ -ATPase α -subunit had abnormal canaliculi and were devoid of typical tubulovesicular membranes.

Regions of Association in the Oligomeric Structure

There has been much suggestive evidence that the α – β heterodimeric H^+,K^+ -ATPase exists as an oligomer. Such evidence includes target size by irradiation and unit cell size of the enzyme in 2D crystals. Using Blue native gel separation and cross-linking with Cu^{2+} -phenanthroline, it was shown that the enzyme did indeed exist as an $(\alpha\beta)_2$ heterodimeric dimer. Membrane-bound H^+,K^+ -ATPase reacted with

Cu-phenanthroline to provide an α - α dimer. The site of Cu²⁺-oxidative cross-linking was at either cys⁵⁶⁵ or cys⁶¹⁶. Hence, this region of the α -subunit is in close contact with its neighboring α -subunit. No evidence was obtained for β - β dimerization. ATP prevents this Cu-phenanthroline-induced α - α dimerization. The M7/loop/M8 sector of the α -subunit is tightly associated with the β -subunit. An antibody mAb 146-14 recognizes the region of the α -subunit at the extracytoplasmic face of the M7 segment as well as the β -subunit, a finding consistent with the association found by column chromatography. Using yeast two-hybrid analysis, a fragment Leu855 to Arg922 of the α -subunit was identified to bind the β -subunit. This is at the entrance of the TM8 into the membrane domain.

Kinetics and Conformational Changes of the Gastric H⁺,K⁺-ATPase

The gastric H⁺,K⁺-ATPase exchanges intracellular hydrogen ions for extracellular potassium ions by consuming ATP. The H⁺ for K⁺ stoichiometry of the H⁺,K⁺-ATPase is not clear. There are reports of two different stoichiometries, one or two H⁺ per ATP hydrolyzed. In ion-tight vesicles studied at pH 6.1, the stoichiometry is 2H⁺:1ATP but at full pH gradient where the pH reaches 1.0, this has to fall to 1:1. Probably, protonation of a carboxylic acid in the second ion-binding site at the lower luminal pH is then maintained.

There are several steps in the reaction scheme of the H⁺,K⁺-ATPase. The enzyme is phosphorylated by ATP at asp³⁸⁶. The rate of formation of the phosphoenzyme (EP) and the K⁺-dependent rate of EP breakdown are sufficiently fast to allow the EP to be an intermediate in the overall ATPase reaction. The initial step is the reversible binding of ATP to the enzyme in the absence of added K⁺ ion, followed by an Mg²⁺ (and proton)-dependent transfer of the terminal (gamma) phosphate of ATP to asp³⁸⁶ of the catalytic subunit (E₁-P•H⁺). The Mg²⁺ remains occluded until dephosphorylation. The addition of K⁺ to the enzyme-bound acyl phosphate results in a two-step dephosphorylation. The faster initial step is dependent on the concentration of K⁺, whereas the slower step is not affected by K⁺ concentration. The second phase of EP breakdown is accelerated in the presence of K⁺ but, at K⁺ concentration exceeding 500 μ M, the ratio becomes independent of K⁺ concentration. This shows that two forms of EP exist. The first form E₂P is K⁺ sensitive and converts spontaneously in the rate-limiting step to E₁P, the K⁺ insensitive form. ATP binding to the H⁺,K⁺-ATPase occurs in both the E₁ and the E₂ state, but with a lower affinity in E₂ state (2000 times lower compared to E₁). The effects of H⁺ and K⁺ on formation and breakdown of EP were determined using transient kinetics. Increasing hydrogen ion concentrations on the ATP-binding face of the vesicles accelerate phosphorylation, whereas increasing potassium ion concentrations inhibit phosphorylation. Increasing hydrogen ion concentration reduces this K⁺ inhibition of the phosphorylation rate. Decreasing hydrogen ion concentration accelerates dephosphorylation in the absence of K⁺, and K⁺ on the luminal surface accelerates dephosphorylation. Increasing K⁺ concentrations at constant ATP decreases the rate of phosphorylation and increasing ATP

concentrations at constant K⁺ concentration accelerates ATPase activity and increases the steady-state EP level. Therefore, inhibition by cations is due to cation stabilization of a dephospho form at a cytosolically accessible cation-binding site. The reaction mechanism is similar to that of the Na⁺,K⁺-ATPase.

As Na⁺ is transported as a surrogate for H⁺ at high pH, it is likely that the hydronium ion, rather than the proton *per se* is the species transported. The ions transported inward from the outside face of the pump are Tl⁺, K⁺, Rb⁺, or NH₄⁺. Presumably, the change in conformation changes a relatively small ion-binding domain in the outward direction into a larger ion-binding domain in the inward direction.

The E₁ conformation of the H⁺,K⁺-ATPase binds the hydronium ion from the cytoplasmic side at high affinity. With phosphorylation, the conformation changes from E₁P•H₃O⁺ to E₂P•H₃O⁺ form, which has high affinity for K⁺ and low affinity for H₃O⁺ allowing release of H₃O⁺ and binding of K⁺ on the extracytoplasmic surface of the enzyme. The rapid breakdown of the E₂P form requires K⁺ or its congeners on the outside face of the enzyme. With dephosphorylation, the E₁K⁺ conformation is produced with a low affinity for K⁺, releasing K⁺ to the cytoplasmic side, allowing rebinding of H₃O⁺.

Fluorescein isothiocyanate binds to the H⁺,K⁺-ATPase, inhibiting ATPase activity but not pNPPase activity. Fluorescence of the fluorescein isothiocyanate (FITC)-labeled enzyme, representing the E₁ conformation, was quenched by K⁺, Rb⁺, and Tl⁺. The quenching of the fluorescence by KCl reflects the formation of E₂K⁺. FITC binds at lys⁵¹⁶ in the hog enzyme sequence. This FITC-binding site apparently becomes less hydrophobic when KCl binds to form the E₂•K conformation. In the E₁ form, the FITC region is relatively closer to the membrane and the extracytoplasmic loop relatively hydrophilic. With the formation of the E₂•K form, the FITC region is more distant from the membrane. These postulated conformational changes are, therefore, reciprocal in the two major conformers of the enzyme.

When the gastric H⁺,K⁺-ATPase was cleaved by Fe²⁺-catalyzed oxidation under various ligand, cleavage patterns were different between the different conformations. There are two Fe²⁺ cleavage sites. In Fe²⁺ site1, the parallel appearance of the fragments at ²³⁰ESE, near ⁶²⁴MVTGD, and at ⁷²⁸VNDS upon transition from E₁ to E₂(Rb) conformations were observed. Meanwhile, in Fe²⁺ site2, the fragment near ²⁹⁹HFIH was cleaved independent of conformational changes. These cleavage patterns were the same as those of the Na⁺,K⁺-ATPase. The cleavage data showed that the structural organization and changes in the cytoplasmic domains, association with E₁/E₂ transitions, are essentially the same for the H⁺,K⁺-ATPase, the Na⁺,K⁺-ATPase, and sr Ca-ATPase. N-domain where ATP binds inclines nearly 90° with respect to the membrane and the A-domain rotates by about 110° horizontally during the E₁ to E₂ conformation.

Functional Residues of the H⁺,K⁺-ATPase

When the gastric H⁺,K⁺-ATPase was digested by trypsin in the presence of high concentration of KCl, the tryptic membrane digest showed the presence of Rb⁺ occlusion, that is, stable binding of Rb⁺ in the membrane domain of the catalytic

subunit as found for the Na⁺, K⁺-ATPase. Some regions near the membrane such as the region between gly⁹³ and glu¹⁰⁴ near the M1 segment, the region between asn⁷⁵³ and leu⁷⁷⁶ near the cytoplasmic side of the M5 segment, and the region after the M8 segment, especially the region between ile⁹⁴⁵ and ile⁹⁶³ containing five arginines and one lysine, were K⁺ protected against digestion. Furthermore, when K⁺ was removed from this membrane digest, the M5/M6 hairpin was released from the membrane, showing that M5M6 membrane hairpin is stabilized by K⁺ ions. Proton pump inhibitors such as omeprazole, pantoprazole, lansoprazole, and rabeprazole all bind to Cys813 of M5M6, giving inhibition of activity.

Using site-directed mutagenesis of the gastric H⁺,K⁺-ATPase transfected in HEK293 cells, the M5M6 luminal loop was studied in terms of K⁺ access to the ion-binding domain. Mutations of M5, M5–M6, and M6 regions, such as P798C, Y802L, P810A, C813A or S, F818C, and T823V, and mutations of M7–M8 and M8, such as E914Q, F917Y, G918E, T929L, and F932L, reduced the affinity for SCH28080, a reversible proton pump inhibitor, up to 10-fold without affecting the nature of the kinetics. The L809F substitution in the loop between M5 and M6 resulted in about 100-fold decrease in inhibitor affinity. The C813T mutant showed ninefold loss of SCH28080 affinity. All these data suggest that the binding domain for SCH28080 is at the surface between L809 and C813, where the M5–M6 loop and the luminal end of M6 are located. Mutations of C813 and I816 in M6 and M334 in M4 also showed that the inhibitor binds close to the luminal surface of the enzyme. Mutations of the negatively charged amino acid residue in the α -subunit showed that the carboxyl group of the membrane-spanning domain is important for cation binding. Mutation of E820Q showed decreased K⁺ sensitivity and the dephosphorylation was not stimulated by either K⁺ or ADP, indicating that E820 might be involved in K⁺ binding and transition to the E₂ form of the H⁺,K⁺-ATPase. Mutation of E795 showed a decrease of the phosphorylation rate and the apparent ATP affinity, indicating that E795 is involved in both K⁺ and H⁺ binding. Mutation of E795 and E820 in M5 and M6 resulted in a K⁺-independent, SCH28080-sensitive ATPase activity, due to a high spontaneous dephosphorylation rate. Thus, the sixth transmembrane (M6) segment of the catalytic subunit plays an important role in the ion recognition and transport in the type II P-type ATPase families. When all amino acid residues in the M6 segment of gastric H⁺,K⁺-ATPase α -subunit were singly mutated with alanine, four mutants, L819A, D826A, I827A, and L833A, completely lost K⁺-ATPase activity. Mutant L819A was phosphorylated but barely dephosphorylated in the presence of K⁺, whereas mutants D826A, I827A, and L833A were not phosphorylated from ATP. Amino acids involved in the phosphorylation are located exclusively in the cytoplasmic half of the M6 segment and those involved in the K⁺-dependent dephosphorylation are in the luminal half. Several mutants such as I821A, L823A, T825A, and P829A partly retained the K⁺-ATPase activity accompanying the decrease in the rate of phosphorylation. Substituting three residues in the Na⁺, K⁺-ATPase sequence with their H⁺,K⁺-ATPase counterparts (L319F, N326Y, and T340S) and replacing the TM3–TM4 ectodomain sequence with that of the H⁺,K⁺-ATPase result in a pump that gives 50% of ATPase activity in the absence of Na⁺ at pH 6.

The cation selectivity of the Na⁺, K⁺- and H⁺,K⁺-ATPase would be generated through a cooperative effort between residues of the transmembrane segments and the flanking loops that connect these transmembrane domains. A model that results from these studies and the three-dimensional (3D) structure of the sarcoplasmic reticulum (SR) Ca-ATPase suggests that ion transport occurs between TM4, 5, 6, and perhaps TM8 and that the vestibule around cys813 is the binding domain of both compounds such as omeprazole and SCH28080.

Acid Secretion and the Gastric H⁺,K⁺-ATPase

The H⁺,K⁺-ATPase is present only in the gastric parietal cell and the intercalated cell of the distal renal tubule. In the resting parietal cell, it is present in smooth-surfaced cytoplasmic membrane tubules. Upon stimulation of acid secretion, the pump is translocated to the microvilli of the secretory canaliculus of the parietal cell. This morphological change results in a several-fold expansion of the canaliculus. There are actin filaments within the microvilli and the subapical cytoplasm. In the cytoskeleton system, there is abundance of microtubules among the tubulovesicles. Some microtubules appeared to be associating with tubulovesicles. A large number of electron-dense coated pits and vesicles were observed around the apical membrane vacuoles in cimetidine-treated resting parietal cells, consistent with an active membrane uptake in the resting state. Cultured parietal cells also undergo morphological transformation under histamine stimulation, resulting in great expansion of apical membrane vacuoles. Immunogold labeling of H⁺,K⁺-ATPase was present not only on the microvilli of expanded apical plasma membrane vacuoles but also in the electron-dense coated pits.

There is activation of a K⁺ and Cl[−] conductance in the pump membrane, which allows K⁺ to access the extracytoplasmic face of the pump. This allows H⁺ for K⁺ exchange to be catalyzed by the ATPase.

The covalent inhibitors of the H⁺,K⁺-ATPase that have been developed for the treatment of ulcer disease and esophagitis depend on the presence of acid secreted by the pump. These are acid-activated prodrugs that accumulate in the acid space of the parietal cell. Hence, their initial site of binding is only in the secretory canaliculus of the functioning parietal cell. These data also show that the pump present in the cytoplasmic tubules does not generate HCl.

The upstream DNA sequence of the α -subunit contains both Ca and cyclic adenosine monophosphate responsive elements in the case of the rat H⁺,K⁺-ATPase. There are gastric nuclear proteins present that bind selectively to a nucleotide sequence, GATACC, in this region of the gene. These proteins have not been detected in other tissues. Stimulation of acid secretion by histamine increases the level of messenger RNA (mRNA) for the α -subunit of the pump. Elevation of serum gastrin, which secondarily stimulates histamine release from the enterochromaffin-like cell in the vicinity of the parietal cell, also stimulates the mRNA levels in the parietal cell. H₂ receptor antagonists block the effect of serum gastrin elevation on mRNA levels. It seems, therefore, that activity of the H₂ receptor on the parietal cell determines, in part, the gene expression of the ATPase. It might be expected, therefore, that

chronic stimulation of this receptor would upregulate pump levels, whereas inhibition of the receptor would downregulate levels of the ATPase.

However, chronic administration of these H₂ receptor antagonists, such as famotidine, results in an increase in pump protein, whereas chronic administration of omeprazole (which must stimulate histamine release) reduces the level of pump protein in the rabbit. Regulation of pump protein turnover downstream of gene expression must account for these observations.

Glossary

Electrical driving force A force derived from a potential difference that causes ion movement due to charge repulsion and attraction.

Free energy The amount of energy that can be converted to work in a physical system.

Hydrolysis A chemical reaction in which a compound is split in two by addition of a water molecule that is also split into hydrogen and hydroxyl.

Hypokalemia Lower than normal (<3.5 mEq l⁻¹) concentration of K⁺ in the blood.

Immunoglobulin-like fold A protein fold that is similar to mammalian antibody fold consisting of a sandwich of beta sheets arranged in a Greek key motif.

Phosphorylation/dephosphorylation Addition/removal of a phosphate group to/from an amino acid side chain in a protein.

Type II membrane proteins Proteins that span the membrane only once, and their carboxy terminus resides outside the cell.

Introduction

The Na⁺,K⁺-ATPase, or sodium/potassium pump, is a membrane protein that is ubiquitous in animal cell membranes. Na⁺,K⁺-ATPase was described first by J C Skou in 1957, a discovery that led to the award of the 1997 Nobel prize in chemistry. Na⁺,K⁺-ATPase couples the hydrolysis of one adenosine triphosphate (ATP) molecule to the transport of three Na⁺ ions out and two K⁺ ions into the cell, thus creating the characteristic concentration gradients of these ions across the cell membrane (typically: intracellular Na⁺, 10–20 mM; K⁺, 100 mM and extracellular Na⁺, 140 mM; K⁺, 4.5–5 mM). At rest, the pump converts 20–30% of the cellular ATP production to active Na⁺ and K⁺-transport in kidney, intestine, muscle, heart, central nervous system, and other tissues. The cell utilizes the Na⁺- and K⁺ gradients to drive numerous processes including volume regulation, electrolyte balance, and secondary transport of sugars, amino acids, protons, and many other metabolites. These functions maintain essential physiological processes such as neurotransmission, cardiac contraction, renal function, and intestinal absorption, etc.

The Na⁺,K⁺-ATPase is a member of the P-type family of cation pumps. The catalytic mechanism of P-type pumps involves phosphorylated active site aspartate intermediates. All P-type pumps are inhibited by vanadate. Other members of this family include sarcoplasmic reticulum Ca²⁺-ATPase (SERCA), plasma membrane Ca²⁺-ATPase, gastric H⁺,K⁺-ATPase, plant and yeast H⁺-pumps (type II, 10 trans-membrane segments), a variety of heavy metal pumps (type I, six trans-membrane + two extra trans-membrane segments), and several homologous gene products of unknown function. The human genome contains 38 P-type sequences, but only 17 of known function.

Subunits and Isoforms

The minimal functional unit of the Na⁺,K⁺-ATPase consists of two subunits, α and β , that are separate polypeptide chains

encoded by separate genes. The α subunit is the catalytic moiety of the pump, numbering about 1000 residues, arranged in 10 trans-membrane segments with three intracellular domains, and contains the binding sites for ATP, Mg²⁺, Na⁺, and K⁺, and the cardiac glycoside inhibitors. The β subunit, consisting of about ~300 residues, is a type II membrane protein with a single trans-membrane segment, and associates with very high affinity to α , to form an $\alpha\beta$ complex. The β ectodomain contains three conserved disulfide bridges and three glycosylation sites. The presence of a β subunit is unique for the K⁺-counter-transporting P-type ATPases, such as Na⁺,K⁺-ATPase and gastric and colonic H⁺,K⁺-ATPase. The β subunit is required for stabilizing the pump, targeting it to the cell membrane, and modulating K⁺ affinity.

In mammals, there exist four known isoforms of α and three of β , combinations of which are expressed and distributed in a tissue- and development-specific manner throughout the body. The isoforms are highly homologous proteins with 70–90% sequence identity. α_1 is found in nearly all tissues and is considered the housekeeping isoform. In the adult human heart, α_1 , α_2 , and α_3 are expressed but the most prominent one is α_1 . Skeletal muscles express α_1 and α_2 predominantly. In neurons, α_1 and α_3 are abundant, and α_1 and α_2 in glial cells. α_4 is expressed uniquely in sperm and is important for motility (Table 1). Each isoform has functional properties that optimally maintain the Na⁺ and K⁺ gradients in the different tissues. Table 1 summarizes the chromosomal location and tissue-specific expression of the isoforms.

Another type of membrane proteins, FXYD proteins, regulate Na⁺,K⁺-ATPase activity in a tissue- and isoform-specific manner. FXYD proteins are a family of seven accessory subunits (in mammals), named after a conserved FXYD motif, which have a single trans-membrane segment, and directly associate with the $\alpha\beta$ complex. FXYD proteins modulate functional properties of the pump, such as the affinity for Na⁺ or K⁺ ions, but are not essential for Na⁺,K⁺-ATPase activity (see Table 2 and Figure 1).

Table 1 Human genes of Na⁺,K⁺-ATPase proteins: Isoforms of α and β subunits are expressed from individual genes

<i>Isoform</i>	<i>Gene</i>	<i>Human chromosome</i>	<i>Amino acid residues</i>	<i>Cell or tissue-specific expression</i>
$\alpha 1$	ATP1A1	1p13.1	1023	Constitutive, ubiquitous, dominant in epithelia of kidney, glands, and intestine
$\alpha 2$	ATP1A2	1q23.2	1020	Brain, muscle, and heart
$\alpha 3$	ATP1A3	19q13.2	1013	CNS and brain
$\alpha 4$	ATP1A4	1q21–q23	1029	Testis and spermatozoa
$\beta 1$	ATP1B1	1q24.2	303	Ubiquitous, like the $\alpha 1$ -subunit
$\beta 2$	ATP1B2	17p13.1	290	Brain, adhesion molecule (AMOG), and liver
$\beta 3$	ATP1B3	3q23	279	Mostly in neural tissue, heart, kidney, and lung

FXYD7		19q13.13	80	

Reaction Mechanism

The reaction mechanism of Na⁺,K⁺-ATPase activity, commonly referred to as the ‘Post-Albers cycle’ depicted in [Scheme 1](#), is the generally accepted scheme to describe the sequence of coupled cation transport and biochemical reactions. The mechanism involves specific Na⁺-catalyzed phosphorylation and K⁺-catalyzed dephosphorylation reactions of the active site aspartic acid residue, and switching between two conformational states: E₁ and E₂. The E₁ conformation binds 3Na⁺ with high affinity and 2K⁺ ions with low affinity at the intracellular surface, while the E₂ conformation binds 2K⁺ ions with high affinity and 3Na⁺ ions with low affinity at the extracellular surface, respectively. During the transport cycle the ions become transiently occluded – inaccessible to the medium on either side of the membrane – resulting in the occluded states, E₁P(3Na) and/or E₂(2K). Efflux of 3Na⁺ ions from the cell is associated with phosphorylation by ATP followed by the conformational change E₁P–E₂P, while the influx of 2K⁺ ions is associated with rapid dephosphorylation of E₂P and the conformational change E₂(2K) → E₁, which is accelerated by binding of ATP with a low affinity.

In normal cells containing mitochondria, the free energy of ATP hydrolysis is close to 60 kJ mol^{−1} and the electrical driving force of the Na⁺,K⁺-ATPase is close to 600 mV (G/F ; where F is Faraday’s constant (96 485 C mol^{−1})). Most of the electrochemical work (~390 mV) is used for the outward translocation of three Na⁺ ions per cycle against the inside negative membrane potential and the 10-fold-steep chemical gradient for Na⁺ ions. Less energy (~40 mV) is used for the inward transport of two K⁺ ions per cycle since potassium in most cells is close to electrochemical equilibrium.

The stoichiometry of 3Na⁺/2K⁺ transported per ATP hydrolyzed is maintained over a wide range of electrolyte compositions. Due to the unequal quantities of charge transported in opposite directions, the pump produces an electric current, in which a net positive charge is extruded from the cell. This property of the ion pump is called ‘electrogenicity’. Thus, the pump is also sensitive to the membrane potential – the binding and release of one of the three Na⁺ ions is the major voltage-dependent step. Because the Na⁺ and K⁺ transport is sequential, it is possible to study separately the Na⁺- and K⁺-transport pathways and the associated charge movement.

Structure of the Na⁺,K⁺-ATPase

A proper understanding of the question “How does a cation-pump pump cations?” requires knowledge of the molecular structure. Since the essence of active Na⁺ and K⁺ pumping is the coupling of the phosphorylation and dephosphorylation steps to the E₁ and E₂ conformational changes, the crucial issues concern the nature of the ATP and cation-binding sites, and structural events accompanying the conformational changes.

The first structure of the heterodimeric P-type ATPase, Na⁺,K⁺-ATPase, isolated from pig kidney, at 3.5 Å, was published in 2007, 50 years after its discovery. This structure contains α , β , and FXYD2 (γ) subunits but only the α and trans-membrane segments of β and (γ) subunits were resolved. A very recently published crystal structure of the Na⁺,K⁺-ATPase from shark rectal gland at 2.4 Å resolution, also in (2Rb)₂–MgF₄^{2−} conformation (Rb⁺ is an analog of K⁺, MgF₄^{2−} is a phosphate analog), shows the subunits of α , β , and the FXYD protein

Figure 1 The structure of the shark rectal gland Na^+, K^+ -ATPase, rendered from the protein data bank (PDB) file 2zxe. The trans-membrane helices of the α subunit are colored green and the A, N, and P domains are colored magenta, cyan, and orange, respectively. The β subunit is in blue and FXD10 is red. The red spheres represent bound K^+ ions.

Scheme 1 The Post-Albers scheme.

(referred to as FXD10), their folds, secondary structures and side-chain rotamers, including the resolved extracellular domain of the β and FXD subunits (see Figure 1).

The α Subunit – The Cation-Pumping Mechanism

The α subunit of Na^+, K^+ -ATPase consists of head, stalk, and membrane sectors. The α subunit has 10 trans-membrane segments and the two Rb^+ ions are occluded approximately in the center of trans-membrane segments M4, M5, and M6. Helices

M4 and M6 are unwound in the middle to enable ion binding. The cytoplasmic part of the pump is made up of three distinct α domains: N for nucleotide binding, P for phosphorylating, and A for actuator. These domains are intimately involved in the pumping mechanism. The A-domain, connected to the M1–M3 helices with rather long linkers, works as the actuator of the trans-membrane gating mechanism that regulates cation binding and release. The P-domain contains the phosphorylated aspartate residue, Mg^{2+} -coordinating residues, and other residues that characterize the Na^+, K^+ -ATPase as members of the haloacid dehalogenase superfamily. The A-domain contains one of the signature sequences, the Thr–Gly–Glu–Ser (TGES) motif, which plays an important role in the processing of the aspartylphosphate intermediate. The P-domain has a wedge shape that is a key in the conversion of A-domain rotational movements to the vertical movements (i.e., perpendicular to the membrane) of the trans-membrane helices. The N-domain, formed by a long insertion between two parts of the P-domain, connected by flexible linkers, contains the residues for adenosine binding and those critical for bridging ATP and the P-domain.

Although we are concerned primarily with Na^+, K^+ -ATPase, it was the advent of the molecular structures of the rabbit sarcoplasmic endoplasmic reticulum calcium ATPase (SERCA1) in 2000 that provided the breakthrough in our understanding of the working of all cation pumps. The structure of Ca^{2+} -ATPase has now been determined in all major conformations of the catalytic cycle. Since the basic principles of the cation pumping mechanism of Na^+, K^+ -ATPase in Scheme 1 are shared by all P-type ATPases, a number of general insights have emerged.

In SERCA, the sequence of structural changes in the pump that constitute the different pumping stages are depicted in cartoon form (see Figure 2):

1. In the E_1 conformation, two Ca^{2+} are bound in the high-affinity sites formed by trans-membrane helices M4, M5, M6, and M8. The cytoplasmic gate is open and bound Ca^{2+} exchange with those in the cytoplasm. The M1 helix is deeply embedded in the lipid bilayer.
2. In E_1 , ATP binds and cross-links the P- and N-domains, so that the gamma-phosphate of ATP and a Mg^{2+} bind to the P-domain to bend it. The N-domain is fixed in a highly inclined position and makes contact with the A-domain in a strained position. The M1 helix is pulled up and bent so that the top of the trans-membrane part closes the cytoplasmic gate of the Ca^{2+} -binding sites.
3. Phosphoryl transfer of the active site aspartate allows dissociation of ADP from $\text{E}_1\text{-P}$, which triggers the opening of the N- and P-domain interface; the A-domain rotates so that the TGES motif wedges into the gap and interacts with the phosphorylation site in the P domain. The separation of N and P domains and creation of interactions between the cytoplasmic A and P and A and N domains is a major characteristic of the E_1P to $\text{E}_2\text{-P}$ conformational change.
4. These movements of the cytoplasmic domains are coupled to marked rearrangement of the trans-membrane helices M1–M6; large downward movements of M4, sharp bending of M5, and rotation of M6 destroy the Ca^{2+} -binding sites.

Figure 2 A cartoon illustration of the architecture of SERCA and the structural changes occurring during conformational transitions. See detailed description in text. Adapted from Toyoshima C (2009) How Ca^{2+} -ATPase pumps ions across the sarcoplasmic reticulum membrane. *Biochimica et Biophysica Acta* 1793: 941–946.

The lower sections of M1 and M2 push against M4, opening the luminal gate and releasing the bound Ca^{2+} into the lumen. 2H^+ ions then bind to the $\text{E}_2\text{-P}$ from the extracellular surface.

5. The glutamate residue in the TGES loop of the A-domain fixes a particular water molecule and catalyzes its attack on the aspartylphosphate. The release of the phosphate and Mg^{2+} unbends the P-domain. This in turn releases M1 and M2 so that M4L closes the luminal gate on the bound 2H^+ ions.
6. In the last step of the cycle, the reverse conformational change from E_2 to E_1 , driven by ATP binding to E_2 , brings the cation-binding sites back into contact with the intracellular medium, the N and P domains come into proximity and the A domain is displaced from the P domain.

In summary, the P- and N-domains change interfaces and thereby control the position of the A-domain, the actuator of trans-membrane gates. ATP, phosphate, Mg^{2+} , and Ca^{2+} are the modifiers of the interfaces. Energy barriers between the principal intermediate states seem to be comparable to the thermal energy; the enzyme has evolved to utilize thermal energy as the driving force for the pumping activity.

While the general mechanism of all P-type ATPase must be similar to that in Figure 2, a major difference between Na^+, K^+ -ATPase and Ca^{2+} -ATPase is the selectivity for the transported cations ($3\text{Na}^+/2\text{K}^+$ vs. $2\text{Ca}^{2+}/2\text{H}^+$), including the third

unique Na^+ site in Na^+, K^+ -ATPase. The cation-binding residues in the occlusion sites are similar for the Na^+, K^+ -ATPase and Ca^{2+} -ATPase, except two conserved residues. Apparently, it is differences in the positions of the side chains and water molecules that mainly define the cation selectivity in occlusion. There is also considerable overlap between the residues that coordinate the two K^+ ions in the E_2 structure of Na^+, K^+ -ATPase, and those expected to coordinate the first two Na^+ ions in the E_1 form (corresponding to the residues that bind Ca^{2+} in the E_1 structure of SERCA1), supporting the notion that both cations use the same occlusion cavity. The third sodium transport site, which is a unique feature of the Na^+, K^+ -ATPase is proposed to be located between M6, M8, and M9. The carboxy terminus of the alpha-subunit (KETYY) is contained within a pocket between trans-membrane helices, and may be a novel regulatory element controlling sodium affinity. Another interesting feature is a regulatory K^+ -binding site, located in the P domain, which may play a role in activation of dephosphorylation and stabilization of the dephosphorylated E_2 conformation.

The β Subunit, FXYD Proteins, and Other Insights

The recent structure of the Na^+, K^+ -ATPase provides an answer to one of the biggest conundrums in the field: the structure and interaction site of the β subunit. This cannot be inferred

from the structure of Ca²⁺-ATPase, which lacks a β subunit. The β subunit is visible with its single trans-membrane segment slanted at 32° to the membrane normal, forming numerous contacts with α M10 and M7. The β ectodomain covers the extracellular loops of the α subunit and can be roughly divided into two subdomains, C- and N-terminal, that form many salt bridges with residues in extracellular loops connecting α trans-membrane segments. The C-terminal ectodomain has an immunoglobulin-like fold. The β subunit also has a short intracellular domain, which was not resolved.

A unique feature of the α subunit of the Na⁺,K⁺-ATPase is an unwound part and kink in M7 and at the cytoplasmic end of M10, which interact with the β subunit. It has been proposed that the unwound part of α trans-membrane M7 and the interaction with β is of central importance to stabilize K⁺ binding within the protein, thus providing a possible explanation of the unique requirement of a β subunit in K⁺-transporting ATPases.

In addition to its stabilization role, the ectodomain of β 1 has also been strongly implicated in epithelial cell adhesion, and β 2 in neural adhesion in the rat brain. The C-terminal lobe of the ectodomain, with its immunoglobulin-like fold, may be crucial for the cell adhesion function, perhaps forming hetero- or homodimers with other cell adhesion molecules that, typically, also contain immunoglobulin-like domains involved in protein-protein interactions.

The single trans-membrane helix of the FXDY protein is close to and interacts with α M9. This has an interesting functional implication, since it is near the proposed location of the third Na⁺-binding site between M6, M8, and M9. Thus, interactions of the trans-membrane segments of FXDY proteins may modulate the binding affinity of Na⁺ ions via the unique third Na⁺ site. The α , β , and FXDY subunits also make contact together close to the outer membrane leaflet, where residues in both α and β subunits and the FXDY residues form a hydrophobic pocket, providing a rationale for this conserved motif.

A specifically bound cholesterol molecule was observed in the shark Na⁺, K⁺-ATPase structure. This molecule is fully resolved and resides in a crevice formed by the trans-membrane helices of β , α M7, and M5. It also plays a role in shielding the unwound part trans-membrane of M7 from bulk lipid and is likely to be involved in stabilizing α/β interactions. Cation pumps are embedded in the phospholipid bilayer of the membrane. Thus, the physical properties of the lipid bilayer can play an important role in their function and stability, for example, by variation in bilayer fluidity and so-called hydrophobic matching with the trans-membrane segments of the protein. In addition, there is also substantial evidence for direct interactions with phospholipids, such as phosphatidylserine and also cholesterol. The new structure provides direct evidence for such a direct interaction with cholesterol.

Physiological Functions of Na⁺,K⁺-ATPase

The α 1 β 1 Na⁺,K⁺-ATPase is constitutively expressed in most cells and it maintains the Na⁺/K⁺ gradients driving the active

transcellular transport in kidney, intestine, lung, and various glands. There is a close relationship between the capacity for reabsorption of Na⁺ in these tissues and the abundance of α 1 β 1 Na⁺, K⁺-ATPase in the basolateral membranes of the epithelial cells. The Na⁺,K⁺-ATPase in human kidneys hydrolyzes over 2 kg of ATP per day and over 600 g of sodium is reabsorbed per day. Accordingly, ouabain-binding data reveal 40–50 million Na⁺,K⁺-ATPase pumps per cell in thick ascending limbs of Henle (TALH) or distal convoluted tubules (DCTs) in kidney, as compared to a few hundred in red blood cells or a few thousand pumps in other nonpolarized cells. In all tubular cells, the Na⁺,K⁺-ATPase maintains electrochemical gradients for sodium ($\Delta\mu_{\text{Na}^+}$), the driving force for secondary active transport of other solutes and ions, such as H⁺, Ca²⁺, and Cl[−]. In the TALH, the Na⁺,K⁺-ATPase functions in concert with the Na⁺,K⁺,2Cl[−] cotransporter and channels for K⁺ or Cl[−] to bring about transcellular NaCl transport. NaCl is reabsorbed at very high rates, while luminal and cytoplasmic Na⁺ concentrations remain relatively high; 20–40 mM in the lumen of TALH. In TALH the γ -subunit (FXDY2) is expressed with the α 1 β 1 Na⁺,K⁺-ATPase. The α 1 β 1 Na⁺,K⁺-ATPase complex has a relatively low affinity for [Na⁺]_{cyt} and it is expressed at very high densities in the basolateral membranes of the TALH.

In the inner medullary collecting duct (IMCD), Na⁺,K⁺-ATPase functions are integrated with those of the sodium channel, epithelial Na channel (ENaC), and K⁺-channels to drive reabsorption of Na⁺ under the regulation of aldosterone. In the IMCD, the expression of FXDY4 or corticosteroid-induced factor (CHIF) is stimulated by aldosterone and the CHIF- α 1 β 1 Na⁺,K⁺-ATPase pump complex has a relatively high affinity for [Na⁺]_{cyt}, thus enabling the pump to reduce the concentration of Na⁺ to 2–5 mM in the tubular lumen and in the cytoplasm of the principal cells of the IMCD. Aldosterone also regulates Na⁺ reabsorption driven by α 1 β 1 Na⁺,K⁺-ATPase in epithelia of lung, glands, and colon, thus providing a major force in the regulation of Na⁺ metabolism and extracellular fluid volume.

Extensive analyses have been performed to clarify the tissue-specific gene expression and the molecular mechanisms of regulation of the α and β -subunit genes (Table 1). Experiments on animal models allow reverse genetic strategy to analyze the function of transport proteins. Targeted disruption of the α 1- and α 2-subunit isoforms in mice confirms that the Na⁺, K⁺-ATPase is essential for life of all mammalian cells. Egg cells lacking both copies of the ubiquitous α 1-isoform do not pass the blastocyst stage. Homozygote knockouts of the α 2-isoform results in death few minutes after birth of the mice apparently due to malformation of neural connections in the medulla oblongata. Knockout of one of the genes shows that α 1- and α 2-isoforms have different physiological functions. An increased force of contraction of the heart is seen in animals lacking one copy of the α 2-isoform, whereas the force of contraction is reduced after elimination of one copy of the α 1-isoform. There is a correlation between the expression of the α 2-Na⁺, K⁺-ATPase, and the Na⁺/Ca²⁺ exchanger in plasma-membrane domains overlaying the endoplasmic reticulum (ER). Elevation of local [Na⁺]_{cyt} may therefore increase the [Ca²⁺]_{cyt} concentration in the space of the cytosol near the ER and thus amplify the force of contraction. This may explain the specific role

of the α_2 -isoform as a regulator of calcium and the force of contraction in the heart.

In skeletal muscle, long-term regulation involves thyroid hormone-mediated changes of the expression level of Na⁺,K⁺-ATPase. Short-term regulation of the Na⁺,K⁺-ATPase is mediated either by changes in intracellular Na⁺ concentration or by hormone-mediated protein kinase reactions leading to changes of the Na⁺,K⁺-ATPase transport properties or in its cell-surface expression. Insulin causes translocation of α_2 Na⁺,K⁺-ATPase to the cell surface, and the α_2 Na⁺,K⁺-ATPase in skeletal muscle is involved in specific regulation in response to hypokalemia. Exercise stimulates exocytosis of α_1 - and α_2 Na⁺,K⁺-ATPase to the plasma membranes of muscle cells and this response is important for recovery of K⁺ after repetitive muscle contractions. Phospholemman (FXYP1) interacts with α_1 and α_2 Na⁺,K⁺-ATPase and modulates their properties to cause a decrease in the affinity to Na⁺. The presence of Na⁺,K⁺-ATPase with low affinity can also be important for the recovery process after muscle contractions. Skeletal muscles are the main intracellular store of K⁺ and the Na⁺,K⁺-ATPase in the sarcolemma (along with H⁺,K⁺-ATPase) is important for maintaining plasma K⁺ concentration in kidney and colon.

The isoforms α_1 – α_3 are expressed in the central nervous system. During embryogenesis, the α_2 Na⁺,K⁺-ATPase is expressed in most regions of the brain and is important in the modulation of neuronal activity in the neonate. In the adult, α_2 Na⁺,K⁺-ATPase is expressed primarily in astrocytes, where glutamate is transported in a sodium- and potassium-dependent fashion. FXYP7 has been identified as an isoform-specific regulator of the Na⁺,K⁺-ATPase in the brain. The properties of α_3 Na⁺,K⁺-ATPase pumps may allow reuptake of K⁺ at low extracellular activities in the brain.

Cardiac Glycosides

Cardiac glycosides are a family of steroids that bind and inhibit the Na⁺,K⁺-ATPase with high selectivity and affinity. Traditionally, these substances were extracted from plants such as *Digitalis purpurea* or foxglove (digitalis), *Strophanthus gratus* (ouabain) or amphibian skin (Bufo marinus-bufalin, marinobufagenin). Ouabain (Somali-waabaayo) was used as an arrow poison in hunting and war. Cardiac glycosides are produced endogenously in mammals as well as plants. Several different cardiac glycosides have been identified in mammalian tissues including the cardenolides ouabain and digoxin, and several bufodienolides including marinobufagenin (see Figure 3). Endogenous cardiac glycosides are intimately involved in control of blood pressure and renal natriuresis. Endogenous

ouabain is synthesized from steroid precursors in the zona glomerulosa and zona fasciculata cells of the adrenal cortex, similar to other steroid hormones.

Cardiac glycosides, particularly digoxin, have been used in the clinic for over 200 years. At therapeutic levels, they exert a positive inotropic effect (an increase in contractile force) on the heart muscle, thus improving circulation in cases of insufficient cardiac output. The positive inotropic mechanism of cardiac glycosides is thought to be mediated by a local increase of Na⁺ concentration in cardiac myocytes due to inhibition of the Na⁺,K⁺-ATPase. This local increase of [Na⁺]_{cyt} reduces extrusion of Ca²⁺ by the Na⁺/Ca²⁺ exchanger, leading to an increase in cytoplasmic Ca²⁺ concentration. Consequently, SERCA-mediated Ca²⁺ load in the ER is enhanced, and more Ca²⁺ is released from the ER into the cytoplasm following excitation. Through the actin/myosin system, the higher cytoplasmic Ca²⁺ causes an increase in force of contraction of cardiac muscle. Digoxin also increases vagal activity through its action on the central nervous system, thus decreasing the conduction of electrical impulses through the atrioventricular (AV) node. This negative chronotropic effect (slowing of heart rate) is important for its clinical use in different arrhythmias.

Experiments with genetically engineered mice support a central role of the α_2 isoform in mediating the inotropic effect of cardiac glycosides and preferential modulation of Ca²⁺ transients and SR Ca²⁺ release in cardiac myocytes, compared to α_1 . Digoxin, the principal cardiac glycoside used in the clinic today, has a narrow therapeutic window due to toxicity caused by Ca²⁺-overload. This overload, produced by excessive inhibition of the Na⁺,K⁺-ATPase in the myocytes, leads to arrhythmia and is potentially lethal. Thus, an α_2 -specific cardiac glycoside could exert the positive inotropic effect without the untoward side-effect of Ca²⁺ overload due to general cardiac Na⁺,K⁺-ATPase inhibition. Recent work shows that digoxin is itself moderately α_2 -selective.

A recently published high-resolution crystal structure of ouabain bound to the shark rectal gland Na⁺,K⁺-ATPase in the E₂(2 K) conformation provides insight into the inhibition mechanism of cardiac glycosides (Figure 4). In this structure, ouabain is seen to bind parallel to the membrane normal, wedged deep in a cavity formed by M1–M5, with its lactone ring embedded deep into the trans-membrane segments, in close proximity to the two occluded K⁺ ions. The structure shows how ouabain can block the ion pathway thereby preventing any transport. However, it is known that K⁺ and ouabain are antagonistic, and thus this model represents a low-affinity structure. A model of the high-affinity conformation, E₂P, suggests that high affinity for ouabain is created by the movement of the M1–M2 trans-membrane segments that forms

Figure 3 The chemical structures of ouabain, digoxin, and marinobufagenin.

Figure 4 The structure of the shark rectal gland Na^+ , K^+ -ATPase in the $\text{E}_2(2\text{K})$ conformation with bound ouabain, rendered from the PDB file 3a3y. The coloring scheme is similar to Figure 1. Ouabain is rendered in magenta sticks. (a) side view of the trans-membrane stalk and (b) view into the cavity formed by M1–M5 from the extracellular direction.

a complementary surface with the bound steroid and prevents its dissociation. This complementary interface cannot be optimally formed in the presence of occluded K^+ that prevents the closure of the cavity formed by M1–M5 on the ouabain molecule, thus explaining the classical K-ouabain antagonism.

In addition to their classical roles as inhibitors of active Na^+ and K^+ transport, there is now compelling evidence that endogenous cardiac glycosides are hormones involved in signal transduction processes, and affect cell growth and proliferation, the Na^+ , K^+ -ATPase acting as the hormone receptor. One signal pathway shown to be involved in kidney and cardiac cell proliferation is ouabain-induced activation of phosphatidylinositol-3-kinase (PI3K) that interacts at the N-terminal end of α subunit, and then Ca^{2+} -dependent phosphorylation of Akt (protein kinase B). Another signaling pathway that ouabain was found to activate is the Src-EGFR-Ras-Raf-Erk cascade that controls gene expression, differentiation, and apoptosis. These effects of ouabain may involve protein–protein interactions, and the signaling complexes are located in microdomains or caveolae, similar to other cellular-signaling complexes. In cancer cells, these signaling pathways may also be involved in effects of cardiac glycosides to stimulate apoptosis, suggesting the possibility of use of cardiac glycosides in anti-cancer therapy – new uses for an old drug. In short, endogenous cardiac glycosides serve as regulators of blood pressure, as well as hormones that influence gene expression, exerting their effects through various cellular pathways, whether in direct response to the changes in Na^+ concentration or through protein–protein interaction networks.

Glossary

Fusicoccin A compound toxic to plants that is produced by the fungus *Fusicoccum amygdali*.

Glycolysis regulation 1 (Gcr1) Yeast transcription factor that acts together with Rap1 to increase expression of some glycolytic enzymes.

Proteasome A large cytosolic protease complex that is responsible for intracellular protein degradation.

Translation upstream factor 1/Repressor activator protein 1/General regulatory factor 1 (Tuf1/Rap1/Grf1) Yeast transcription factor involved in a variety of cellular processes including telomere regulation, chromatin silencing, and glycolysis.

Plasma-membrane H⁺ pumps (also known as H⁺-ATPases) are widely distributed throughout the fungal and plant kingdoms. They use the energy from adenosine triphosphate (ATP) hydrolysis to generate a sizable electrochemical gradient across the surface membrane, which in turn drives nutrient uptake into the cell via a series of H⁺-coupled co-transporters (**Figure 1 (a)**). The proton-pumping activity of the adenosine triphosphatase (ATPase) also contributes to the regulation of intracellular pH. The genes encoding representative members of the family have been cloned from budding (*Saccharomyces cerevisiae*) and fission (*Schizosaccharomyces pombe*) yeast, *Neurospora crassa*, several pathogenic fungi, and numerous plant species including *Arabidopsis thaliana*, *Nicotiana plumbaginifolia* (tobacco), and *Lycopersicon esculentum* (tomato).

Introduction

The fungal and plant plasma-membrane H⁺-ATPases belong to a ubiquitous family of cation pumps known as P-type ATPases, so named because they hydrolyze ATP via a covalent aspartyl-phosphate reaction intermediate. When the P-ATPases are classified based on sequence alignments, membrane topology, and the nature of the transported cation(s), H⁺-ATPases fall into a category designated as P₂ or type III.

Since 1986, when the *PMA1* genes of *S. cerevisiae* and *N. crassa* were cloned and sequenced, these two H⁺-ATPases have served as prototypes for the group as a whole. Yeast, in particular, has proven to be an extremely useful model system. A feature of considerable value in the molecular characterization of the yeast *PMA1* ATPase is its abundance in the plasma membrane, where it constitutes up to 25% of total protein. By virtue of the ease with which site-directed yeast mutants can be made and analyzed, an extensive collection of *pma1* mutants has been generated covering the entire length of the protein, and this resource continues to provide molecular details as to the structure and function of the H⁺-ATPase. Finally, the use of yeast as a vehicle for heterologous expression of other ATPases, such as the individual isoforms of plant H⁺-ATPase, has enabled researchers to study specific features of these enzymes that could not be analyzed in their natural setting. Recently, such studies culminated in the publication of the first high-resolution crystal structure of a P-type proton pump (see section **Structure**).

Just as the P-type ATPases of animal cells are of paramount importance to cellular homeostasis, fungal and plant H⁺-ATPases are essential enzymes whose function is fundamental to the viability of the host organism. As a cell surface component that is common to all fungi examined to date, the H⁺-ATPase has potential clinical significance as a target for antifungal drug development. Specific, high-affinity inhibitors would most likely be fungicidal and may not even be required to enter the cell, thus avoiding multidrug resistance (MDR) efflux pumps and reducing the likelihood of toxic effects on host cells. Plant H⁺-ATPases perform a multiplicity of tissue-specific roles that include nutrient uptake in roots, opening of leaf stomata, seed coat development, and pollen formation. A better understanding of the structure, function, and regulation of these enzymes will have far-reaching effects of agricultural and economic significance.

Structure

At the structural level, the fungal and plant plasma-membrane H⁺-ATPases are 100-kDa polypeptides that are deeply embedded in the lipid bilayer, requiring detergents for solubilization. The N- and C-termini of the H⁺-ATPase are both located in the cytoplasm. As in other P₂-type ATPases, each H⁺-ATPase has 10 hydrophobic transmembrane α -helices, four (M1–M4) at the N-terminal end and six (M5–M10) at the C-terminal end. This membrane (M) domain anchors the large (almost 400 amino acids) cytoplasmic loop in the center of the polypeptide containing the critical catalytic sites that bind ATP and form the aspartyl-phosphate intermediate.

The first three-dimensional (3D) glimpse of H⁺-ATPase structure came from cryoelectron microscopic maps of the *N. crassa* fungal enzyme at 8-Å resolution. Over the past few years, this low-resolution view has been extensively updated by comparison with X-ray crystallographic structures of the related mammalian sarcoplasmic reticulum Ca²⁺-ATPase (SERCA1a), for which there are now more than 20 different conformational snapshots. Although the level of amino acid identity between the H⁺-ATPases and rabbit SERCA1a is only around 20%, Kuhlbrandt and colleagues demonstrated that the amino acid sequence of the *Neurospora* H⁺-ATPase could be overlaid upon the Ca²⁺-ATPase template to give a 3D

structure with the same three well-defined cytoplasmic regions representing nucleotide-binding (N), phosphorylation (P), and actuator (A) domains. Much more recently, Pedersen and colleagues compared a 3.6 Å structure of the *A. thaliana* H⁺-ATPase (AHA2) enzyme with equivalent forms of the SERCA1a enzyme, revealing a strikingly similar folding pattern that likely reflects a structure conserved even between different subfamilies of P-type ATPases.

Reaction Mechanism

Like the intensively studied mammalian Na⁺-, K⁺-, and Ca²⁺-ATPases, the fungal and plant plasma-membrane H⁺-ATPases are considered to alternate between two major conformational states (E₁ and E₂) during their reaction cycle (Figure 1(b)). The scale and complexity of domain movements have now been comprehensively mapped in a series of crystal structures of the SERCA1a ATPase. This information, supplemented with details from the AHA2 structure that suggest an elegant and highly plausible model for proton transport across the membrane, is presented in a much simplified form in Figure 2.

Starting with the transient E₂ open conformation, protonation of the membrane-embedded acidic residue that acts as the critical acceptor/donor residue in the proposed H⁺ pathway (Asp⁶⁸⁴ in AHA2) is followed by nucleotide binding in the presence of Mg²⁺ as metal cofactor (E₁). This produces conformational changes that lead to phosphorylation of Asp³²⁹ in

AHA2 (or Asp³⁷⁸ in yeast PMA1) and closure of the structure, bringing the N and A domains into close contact (E₁P). Subsequent rotation of the A domain occurs during the E₁P to E₂P transition, opening a pathway for exit of the H⁺ into extracellular space. This allows for dephosphorylation of the P domain and transition back to the vanadate-sensitive E₂ form to complete the cycle. The physical scale of domain movements made during the reaction cycle is impressive. Measurements based on SERCA 1a structures indicate that the top of the N domain moves more than 50 Å in approaching the A domain, which then rotates 90° to interact with the P domain via a highly conserved TGES motif. Correct positioning and orientation of the A domain on the interactive surface of the wedge-shaped P domain depends on movements of the transmembrane helices perpendicular to the plane of the membrane that are transduced by flexing of the P domain itself.

Detailed information from the plant AHA2 structure suggests a transmembrane proton transport mechanism involving a water-filled cavity that is formed by partial unwinding of M4, and lined with polar or charged side chains contributed by conserved residues in M5 and M6. The proton enters the pathway between M1, M2, and M4, subject to a gating mechanism that relies on hydrogen bonding between Asn¹⁰⁶ and Asp⁶⁸⁴. Asp⁶⁸⁴, a residue located in the center of the membrane in all H⁺-ATPases and known to be essential for H⁺ translocation, is the likely proton-binding site. Upon de-protonation, Asp⁶⁸⁴ is

Figure 1 (a) The plasma-membrane H⁺-ATPase plays an essential role in yeast cell physiology. The pumping of protons (H⁺) across the membrane at the expense of ATP hydrolysis establishes the membrane potential (ΔΨ) required for nutrient import and helps to regulate intracellular pH. PM, plasma membrane. (b) The H⁺-ATPase reaction cycle. See text for explanation. VO₄⁻, vanadate, a potent P-type ATPase inhibitor.

Figure 2 (A) Major domain movements that occur during conversion of the ATPase from the E₁ (cation-bound) to the E₂ (cation-free) conformation. All 10 transmembrane helices are shown but only five are numbered (white). M6, the helix shown in red, includes the embedded proton-binding Asp⁶⁸⁴ residue (—) at the center of a putative H⁺ pathway (see text for further details). Specific residues, including the phosphorylated Asp³²⁹, correspond to those of the plant H⁺-ATPase AHA2. During the E₂-P to E₂ transition, the conserved TGES amino acid motif is involved in dephosphorylation of the aspartyl phosphate (D329) and protection of the unoccupied nucleotide-binding site. N, nucleotide-binding domain; P, phosphorylation domain; A, actuator domain; M, membrane sector formed by 10 transmembrane helices. This cartoon depicts the reaction cycle of a plant H⁺-ATPase (AHA2) but incorporates information derived from the domain movements of the P-type Ca²⁺-ATPase of muscle sarcoplasmic reticulum, as determined by Toyoshima and colleagues.

Figure 3 The yeast secretory pathway. ER, endoplasmic reticulum; SV, secretory vesicles; PM, plasma membrane.

protected from re-protonation by the close proximity of another conserved charged residue (Arg⁶⁵⁵), effectively preventing any retrograde proton transport. The positive charge also serves to stabilize the negatively charged residue, keeping the H⁺ pathway closed. This feature probably accounts for the extremely high membrane potentials generated by plant and fungal H⁺-ATPases compared to their mammalian cation-transporting counterparts. Protons, most likely in the form of hydronium ion (H₃O⁺) complexes, are conducted rapidly across the membrane along proton wires formed by a H-bonded network of water molecules.

Biogenesis

Biogenesis of the H⁺-ATPase begins with its synthesis in the rough endoplasmic reticulum (ER), from which it travels to the plasma membrane via the secretory pathway (Figure 3). Because of its abundance in the membrane, together with the ease of making site-directed mutants, the yeast H⁺-ATPase has served as a valuable model for studying this process.

While still in the ER, the ATPase adopts a fully folded structure that has the protease-resistant characteristics of the mature enzyme at the plasma membrane. The folded molecule is then incorporated into coat protein complex II (COPII) vesicles and shuttled to the *cis*-Golgi. Of particular relevance, a sub-population of COPII vesicles has been identified that preferentially recruits and packages the H⁺-ATPase by virtue of a specific coat protein, Lst1p. At least in principle, this mechanism provides a way to regulate biogenesis, underscoring the significance of the ATPase to the functioning of the cell as a whole.

There is much interest in the structure of the ATPase as it exits the ER. Oligomeric forms of the *Neurospora* H⁺-ATPase have been known for many years and were originally thought to be by-products of detergent treatment. More recent studies, however, have demonstrated the existence of oligomers of the yeast H⁺-ATPase early in biogenesis by three different methods: blue native gel electrophoresis, sucrose gradient centrifugation, and cross-linking of epitope-tagged polypeptides. Oligomer formation also provides a logical explanation for

the effects of dominant-negative *pma1* mutants, which cause co-expressed wild-type H⁺-ATPase to be retained in the ER. The functional significance of the oligomers is not yet clear, given an earlier demonstration that the *Neurospora* H⁺-ATPase is fully active when solubilized and reconstituted as a monomer. There has been speculation that the oligomers may play a special role in the biogenesis and/or storage of the ATPase but neither case has been proven definitively.

Successful transport of the yeast H⁺-ATPase to the plasma membrane depends on its incorporation into detergent-resistant lipid rafts, sterol- and sphingolipid-rich structures into which certain plasma-membrane proteins are segregated en route to the cell surface. Wild-type ATPase becomes associated with rafts prior to exiting the ER and failure to do so compromises its trafficking and stability. The key lipid factor in this process appears to be neither sterol nor sphingolipid *per se*, but rather the saturated C26 very long-chain fatty acid in ceramide, a major component of yeast sphingolipids. Substitution of C26 with shorter fatty acids destabilizes the lipid-ATPase complex, leading to mistargeting and degradation of the ATPase in the vacuole. These findings reinforce the importance of lipid-lipid and lipid-protein interactions for the functional organization of the plasma membrane and the entire lipid raft concept.

Many mutations in the *PMA1* gene that lead to misfolding of the H⁺-ATPase result in arrest of the polypeptide in the ER and massive accumulation of internal membranes. This represents the first level of quality control in biogenesis and, in most instances, is followed by re-direction of the offending ATPase via the ER-associated degradation (ERAD) pathway for digestion in the proteasome. Quality control screening is maintained, however, as the H⁺-ATPase progresses through the secretory pathway. There are several examples of mutant ATPases that escape ER quality control only to be recognized as aberrant and differentially processed at later stages of the secretory pathway by vacuolar proteases. These include mutants with as few as two amino acid substitutions and some with short C-terminal truncations. Although these forms are apparently delivered normally to the plasma membrane, they are short-lived compared to the wild-type enzyme, becoming ubiquitinated and then processed by the endocytic pathway for delivery to the vacuole. Information contained within a stretch of 20 amino acids toward the C-terminus of the yeast ATPase seems to be critical for ER export and stability of the enzyme once it reaches the plasma membrane. It is also apparent that the ATPase is not uniformly distributed throughout the plasma membrane but is restricted to certain compartments, segregated from some other protein components of the membrane such as the proton symporters Can1p and Fur1p.

Regulation

In addition to the major H⁺-ATPase gene (*PMA1*), *S. cerevisiae* and *S. pombe* each have a second gene (*PMA2*) that encodes a nearly identical protein. The expression level of *PMA2* is so poor that it is unable to support growth; however, the physiological function of the second ATPase remains unclear.

By contrast, plants possess multiple H⁺-ATPase genes. In *A. thaliana*, whole-genome sequencing has identified a family

of 11 such genes, most or all of which are expressed in a tissue-specific manner. Where tested, the corresponding H⁺-ATPase isoforms differ detectably in their catalytic behavior, suggesting that enzyme characteristics may be matched to the physiological requirements of individual tissues. While there is undoubtedly some overlap between tissue distribution and ATPase isoforms, there is strong evidence that particular *A. thaliana* H⁺-ATPase isoforms have tissue-specific roles in stomatal opening and closing (AHA1), pollen development (AHA3), and seed coat development (AHA10).

A diversity of environmental conditions and stress factors influence the biosynthesis and the activity of fungal and plant plasma-membrane H⁺-ATPases. In yeast, two mechanisms have been identified that both result in upregulation of the H⁺-ATPase by glucose. At the transcriptional level, addition of glucose to the growth medium leads to a rapid increase in messenger RNA (mRNA) for the H⁺-ATPase, and analysis of the promoter region of the *PMA1* gene has revealed active binding sites for several recognized transcription factors including translation upstream factor 1/repressor activator protein 1/general regulatory factor 1 (Tuf1/Rap1/Grf1) and glycolysis regulation 1 (Gcr1). It is almost certainly significant that the same factors promote transcription of genes encoding glycolytic enzymes, pointing to a coordinated set of mechanisms that enable rapid, efficient growth on glucose.

Because the yeast H⁺-ATPase has an unusually long half-life at the plasma membrane (~11 h), posttranslational mechanisms are required to modulate its activity rapidly. Indeed, within minutes of glucose addition, the yeast ATPase displays an increased V_{max}, a lowered K_m, and a more alkaline pH optimum. It has been confirmed that this ensemble of changes results from posttranslational phosphorylation near the C-terminus of the 100 kDa polypeptide. Initially, detailed mutational analyses linked the glucose-induced change in V_{max} with amino acids Arg⁹⁰⁹ and Thr⁹¹² and the change in K_m with Ser⁸⁹⁹ and Glu⁹⁰¹. Both pairs of residues constitute potential phosphorylation sites and both *in vitro* and *in vivo* evidence suggests that yeast protein kinase 2 (Ptk2)-mediated phosphorylation of Ser⁸⁹⁹ is responsible for the glucose-regulated K_m change. With respect to changes in V_{max}, the application of cutting-edge techniques in mass spectrometry has demonstrated that the sequential phosphorylation of Ser⁹¹¹ and Thr⁹¹² is directly linked with glucose-dependent activation of the ATPase. Phosphorylation of these two tandem residues is required for full activation of the ATPase in response to glucose; therefore, *in vivo*, the ATPase exists in three forms relative to C-terminal phosphorylation – P0, P1, and P2 (glucose activated). Truncation of the C-terminus leads to constitutive activation, suggesting that the domain normally behaves in an auto-inhibitory fashion. Studies using site-directed mutagenesis of the yeast H⁺-ATPase, coupled with suppressor analysis, suggest that the C-terminus interacts with the stalk region near the cytoplasmic surface of the membrane and also with the ATP-binding (N) domain.

In plants, a variety of physiological conditions, such as light, hormones, and salt concentration, can affect the expression of specific ATPase isoforms but precise transcriptional mechanisms have not yet been elucidated. As in yeast, however, the primary modulator of plant H⁺-ATPase activity is the C-terminus (or regulatory R domain) of the enzyme acting in

an auto-inhibitory fashion. In the plant H⁺-ATPase, the penultimate C-terminal residue (Thr⁹⁴⁷ in AHA2) is a phosphorylation target that, when modified, is bound by regulatory 14-3-3 proteins, a highly conserved family of acidic proteins expressed ubiquitously in eukaryotic cells. The 14-3-3 proteins bind as dimers, simultaneously activating the H⁺-ATPase and driving it into a dodecameric quaternary structure consisting of six ATPase units and six 14-3-3 molecules. The mode of action of the fungal toxin fusaric acid is to bind irreversibly to the H⁺-ATPase/14-3-3 complex, constitutively activating the enzyme such that leaf stomata are unable to close, causing the plants to wilt. The R-domain of the plant H⁺-ATPase, which is about 60 amino acids longer than that of the yeast enzyme, includes two short inhibitory sequences, each ~20 residues in length. Removal or mutagenesis of these sequences activates the ATPase, presumably by preventing the sequences from interacting with other sites on the enzyme and/or by improving accessibility of the C terminus for phosphorylation and subsequent 14-3-3 binding. As observed in yeast, mutations at sites distal to the C-terminus of the plant H⁺-ATPase can activate the enzyme. Since these mutations map to the actuator and phosphorylation domains it is likely that these domains house the inhibitory binding sites targeted by the C terminus.

Regulation of H⁺-ATPase activity is achieved through the coordinated action of multiple pathways. Our appreciation of the significance and complexity of this network will increase as our ability to explore cell physiology on a genome-, transcriptome- and proteome-wide basis improves.

Summary

Research into the structure, function, biogenesis, and regulation of fungal and plant plasma-membrane H⁺ pumps continues to provide a wealth of scientific information about the physiology of their host cells. Moreover, these pumps are invaluable as protein models not solely for P₂-type ATPases but for complex integral membrane proteins in general.

Glossary

Bacteriochlorophyll *a* Photosynthetic pigment composed of a tetrapyrrolic ring coordinating a Mg^{2+} ion, present in purple bacteria to operate anoxygenic photosynthesis.

Bacteriopheophytin *a* A molecule of bacteriochlorophyll *a* missing the central Mg^{2+} ion.

Intracytoplasmic membranes (ICMs) System of internal membranes originated from and continuous with the plasmatic membrane, organized in fingerlike intrusions, lamellae, tubules, or vesicles depending on bacterial species.

Membrane P and N faces The positive (P) and the negative (N) faces of the cell membrane, namely the sides that face the phase characterized by a positive or a negative potential.

Midpoint potential The midpoint potential, or $E_{m,7}$, is the potential at which the concentrations of the oxidized and reduced forms of the redox pair are equal, at pH 7.

Ubiquinone One of a class of aromatic diketones in which the carbon atoms of the carbonyl groups are part of the ring structure. This oil-soluble substance is present in plants, animals, and microorganisms as it is a component of the electron transport chain.

Introduction

Purple bacteria form a heterogeneous group of microorganisms capable of growing under anoxic conditions by anoxygenic photosynthesis. They can be divided into purple nonsulfur bacteria, which are able to grow both phototrophically and in darkness, and purple sulfur bacteria, all of them capable to grow in the light but only few of them in the dark. The recent publication of the first complete genome sequence of a purple nonsulfur bacterium, *Rhodospseudomonas palustris*, pointed out the metabolic versatility of this group of bacteria. Indeed, it was found that the genome contains all the genes needed for switching from chemotrophy to phototrophy, from organotrophy to litotrophy, and from heterotrophy to autotrophy. Under anoxic light conditions, *R. palustris* can use either the reducing power deriving from organic compounds, such as organic acids or aromatic compounds, or the electrons deriving from inorganic compounds, such as H_2 or $S_2O_3^{2-}$. When growing chemotrophically in the presence of oxygen, respiration occurs and the reducing power can derive, as well as under anoxic light conditions, from either organic or inorganic compounds. When neither light nor oxygen is present, anaerobic respiration can take place, using NO_3^- or N_2O as final electron acceptors. Moreover, purple sulfur bacteria are able to use sulfide as an electron donor, oxidizing it to elemental sulfur or even to sulfate, while only some nonsulfur bacteria can use S^{2-} , but with different enzymatic pathways.

Due to the remarkable complexity of the metabolism of purple bacteria, this article mainly focuses on the main electron acceptors and donors involved in the photosynthesis and in the respiration.

The Electron Transport Chain

The main stages of both photosynthesis and respiration processes occur in membranes. Therefore, membranes are the site

of adenosine triphosphate (ATP) generation for purple bacteria and in both processes ATP is formed as a result of the proton motive force generated along with electron translocation through the electron transport chain (ETC).

These two processes, however, take place in different sites of the purple bacterial membrane: the cytoplasmic membrane (CM) harbors the components of the respiratory apparatus, while the photosynthetic apparatus is located in the so-called intracytoplasmic membranes, which originate from the invagination of the CM and can take different forms throughout the purple bacteria group. Although oxygenic respiration and anoxygenic photosynthesis would appear to be two distinct and very different processes, they have many common issues.

Anoxygenic Photosynthesis

The specificity of purple bacteria is their ability to form their energy carrier (ATP) in the absence of oxygen by using sunlight as a source of energy. In this process, bacteriochlorophylls are both the primary electron donors and the final electron acceptors, as anoxygenic photosynthesis is a cycle (Figure 1).

A photon is absorbed by the light-harvesting complexes that funnel the excitation toward bacteriochlorophylls in the reaction center (RC) and charge separation occurs. This energy is used for the release of an electron which reduces the quinone Q. Once the quinone is doubly reduced (i.e., after a second photon is captured), it picks up protons from the cytoplasmic space and translocates through the membrane to reach the cytochrome bc_1 complex; here, electrons are addressed to the cytochrome c_2 (Cyt c_2), while protons are released in the periplasmic space. Cyt c_2 is then able to reduce the oxidized primary electron donors in the RC, thus closing the cycle. The protons accumulated in the periplasm form an electrochemical gradient which is used by the ATP synthase to generate ATP.

The electron cycle is opened only by the 'Δp-driven reversed electron transport' (indicated by the thin blue arrows in Figure 1), that is by the action of both the reduced

nicotinamide adenine dinucleotide (NADH) dehydrogenase working in the reversed way to reduce NAD^+ to NADH, and the succinate dehydrogenase also working backwards reducing fumarate to succinate. As these two enzymes are able to catalyze both the forward and reverse reactions, the force that drives the direction is the presence or absence of the products; in particular, the reversed reactions are ways to get rid of the possible excess of the reduced quinol. The reversed NADH dehydrogenase reaction is also the way to refurbish the cell with NADH-reducing equivalents.

Respiration

In the presence of O_2 , anoxygenic photosynthesis in purple bacteria is inhibited and the ATP is synthesized through cellular respiration (Figure 2).

The reducing power carried by NADH is transferred, by the action of NADH dehydrogenase, to a quinone. The quinone can also be reduced by the succinate dehydrogenase, but in this process there is no proton translocation. The reduced quinone migrates through the membrane and can be oxidized both by

the quinol oxidase, with oxygen as the electron acceptor, or by the bc_1 complex, that functions (exactly as in photosynthesis) as a proton-translocating step and transfers the electrons to the Cyt c_2 . This soluble protein is, in respiration, oxidized by the Cyt cbb_3 oxidase which drives the reducing power to a molecule of O_2 . As in photosynthesis, the protons accumulated in the periplasm form an electrochemical gradient which is used by the ATP synthase to generate ATP.

The Role of the Quinone Pool

As discussed above, purple bacteria have a very versatile metabolism. The regulation of the different metabolic behaviors is headed by the RegA/RegB system, which regulates photosynthesis, respiration, and nitrogen and carbon fixation. This regulon gathers an integrated signal inclusive of environmental and cellular stimulations.

An important integrative signal coming from the cell is its redox state, which undergoes different values depending on the different metabolic conditions. This signal is mediated by the quinone pool, which holds a crucial role for the energetic processes in the cell, as it is schematically shown in Figure 3.

Electron Acceptors and Donors Common in Photosynthesis and Respiration

All the above-described processes take place by means of prosthetic groups and protein cofactors.

The Ubiquinol: Cytochrome c Oxidoreductase (or Cytochrome bc_1 Complex)

The ubiquinol:cytochrome c oxidoreductase is part, as previously shown, of both photosynthetic and respiratory ETC as its role is to oxidize the lipid-soluble quinol and transfer its electrons to c -type cytochromes. The overall reaction is the following (eqn [1]), where QH_2 indicates the reduced quinol, while H_c^+ and H_p^+ indicate protons in the cytoplasmic and in the periplasmic space, respectively:

As cytochromes are able to accept only one electron at a time, quinones have to release their reducing equivalents one by one, and this shift from two electrons to a one-electron process is managed by Cyt bc_1 thanks to its architecture and cofactors.

This protein complex is a dimer and each monomer is composed of three subunits and contains four redox-active metal centers forming two distinct ETC: a low potential chain that transfers electron from the Q_P (P = membrane P face) site to the Q_N (N = membrane N face) site through two b -type hemes, namely Cyt b_L (L = low potential) and Cyt b_H (H = high potential), and a high-potential chain, formed by a $[2Fe2S]$ cluster and a c -type heme covalently bound to the protein (Cyt c_1), that makes electrons flow from the Q_P site to the oxidized Cyt c_2 .

The quinol (QH_2) binds to the Q_P site where a bifurcation occurs. The electron that takes the low-potential chain easily passes from the Cyt b_L to the Cyt b_H , as the first has a midpoint potential of about -90 mV and the second of about $+50$ mV. This high-energetic step is necessary to compensate the otherwise unfavorable passage of a negative charge through the membrane from the P to the N face. Close to the Cyt b_H site is located the Q_N site, where a quinone is reduced to semiquinone by the reduced Cyt b_H . This process, which is unfavorable due to this potential difference (from $+50$ to -180 mV), occurs due to the protein-quinone interactions, which make the quinone potential more positive. The semiquinone is held in the Q_N site until a second electron takes the low-potential chain and reduces it to QH_2 .

The electron that takes the high-potential chain reduces the $[2Fe2S]$ cluster, which, in this state, shows a higher affinity to the Cyt c_1 that is almost $25 \text{ \AA}$ away. This affinity makes the protein literally turn close to Cyt c_1 , so that the electron can reach the c_1 -heme. The oxidized $[2Fe2S]$ cluster is then more affine to the Q_P site and turns close to it. Midpoint potentials have been measured for the $[2Fe2S]$ cluster, but the values depend dramatically on the occupant of the Q_P site; with the native Q bond, the midpoint potential is about $+320$ mV; Cyt c_1 has a midpoint potential of about $+230$ mV.

The reduced Cyt c_1 is able to transfer its electron to the Cyt c_2 that would close the photosynthetic cycle reducing the RC's P dimer.

Cytochromes

Cytochrome c_2 is a single-heme soluble periplasm-located protein and acts as an electron deliverer. It accepts electrons from the Cyt c_1 of the bc_1 complex and is present both in the photosynthetic process and in respiration, respectively, it reduces the P^+ dimer to P , which is thus able to start a new photosynthetic turn, or reduces the cytochrome cbb_3 oxidase and in some organisms (*Rhodobacter sphaeroides*) also the cytochrome aa_3 oxidase.

The underlying process for electron transfer at this step is Cyt c_2 docking: many models have been proposed and many kinetic studies have been carried out to determine the Cyt c_2 -RC interaction; it can be said that the docking is possible mainly due to electrostatic interactions, but short-range interactions and H-bonds play a role as well.

After the protein docking, the most likely electron-transfer pathway proceeds from the heme edge via Tyr L162 to the

bacteriochlorophyll dimer, in a microsecond-scale process. The heme midpoint potential varies between +280 and +360 mV, depending on purple bacteria strains.

The RC of *Blastochloris viridis* contains a nondissociating tetraheme cytochrome molecule that facilitates the electrons flowing from Cyt c_2 . The electron transfer between the cytochrome and primary donor is about 3 times faster in *Blc. viridis* than in *R. sphaeroides*. This may be due to a different path length (the distance between conjugated atoms on the heme and primary donor is 12.3 Å in *B. viridis* compared to 14.2 Å in *R. sphaeroides*).

Cytochromes other than Cyt c_2 are synthesized by purple bacteria in different metabolic phases: isocytochrome c_2 and cytochrome c_7 (the latter membrane-bound) are present preferably in the presence of O_2 , while Cyt c_2 transcription is increased in anoxic conditions, thus revealing that Cyt c_2 is mainly involved in photosynthesis, while iCyt c_2 and Cyt c_7 are involved in respiratory pathways.

NADH Dehydrogenase

NADH dehydrogenase is an L-shaped transmembrane complex, the largest of the bacterial electron-transfer complexes as is composed of 14 subunits; electron flow is mediated by a flavin mononucleotide (FMN) cofactor and 9 Fe/S centers, two [2Fe2S] and seven [4Fe4S] as described for *Thermus thermophilus*; one of the tetranuclear clusters is prokaryote specific.

This complex transfers electrons from NADH (−320 mV) to ubiquinone (+90 mV). The primary electron acceptor is FMN (−380 mV), then the electron passes through the linear pathway created by seven [FeS] clusters. The potentials of six of them vary between −300 and −230 mV; the other has a pH-dependent midpoint potential ranging between −20 and −160 mV and is probably the last to be reduced. This enzyme mediates the overall reaction [2] by which four cytoplasmic protons are released in the periplasmic space:

This enzyme can also work in the reverse direction, in particular in phototrophic growth conditions in presence of a high QH_2/Q ratio, to synthesize NADH-reducing equivalents.

Succinate Dehydrogenase

The succinate dehydrogenase is a membrane-bound flavoprotein that is part of both the ETC and the tricarboxylic cycle; it transfers electrons from succinate to quinones, as indicated in reaction [3], and no proton translocation occurs.

This enzyme contains different cofactors that create a track for electrons; namely, a flavin adenine dinucleotide molecule, a [2Fe2S] cluster, a [4Fe4S] cluster, a [3Fe3S] cluster, and a heme b . Depending on the cell energetic needs, the enzyme can also catalyze the reverse reaction, as can happen during photosynthesis (see Figure 1).

Electron Acceptors and Donors Specific of Photosynthesis

The Electron Transfers in the RC

The RC of purple bacteria is an integral membrane protein complex composed of L, M, and H subunits. The H subunit contributes to the complex stability and is involved in proton binding and transfer, while L and M compose the core of the RC and embed nine cofactors, symmetrically disposed in an A and a B branch as shown in Figure 4: two bacteriochlorophyll a molecules that form a dimer (P) connecting the two branches, two monomeric bacteriochlorophyll a molecules (B_A and B_B), two bacteriopheophytin a molecules (H_A and H_B), two ubiquinone molecules (Q_A and Q_B), and an iron ion. Also, some authors suggest the presence of a carotenoid molecule located next to the B_B monomer. Bacteriochlorophylls and bacteriopheophytins can be substituted by some other molecules of the same class.

The midpoint potential of the cofactors is a critical point due to their own nature of electron transfer. The one directly measured is the midpoint potential of the P dimer, that is approximately +500 mV for the P^+/P couple. This positive potential makes it an optimal electron acceptor for Cyt c_2 .

When a photon is conveyed to the P dimer, an electron is raised to a higher-energy level in a femtosecond timescale; as Mg^{2+} is not able to release an electron, the electron comes from the tetrapyrrolic rings of the P dimer. The P^+/P^* couple has a very negative midpoint potential and is very unstable.

The excited dimer P^* transfers the electron, selectively through the A branch, to B_A (in about 3.5 ps, in *R. sphaeroides*). Then, the electron is transferred to H_A (in 0.9 ps, in *R. sphaeroides*); the overall transfer from P^* to H_A takes from 3 to 5 ps, depending on bacterial species. The electron transfer from H_A^- to Q_A takes 200 ps, while the reduction of Q_B to QH_2 takes place much more slowly, in about 100 μs. The oxidized P^+ is reduced back to P by an electron donated by Cyt c_2 : this transfer takes from 0.5 to 50 μs.

Figure 4 Schematic representation of the RC organization. P, dimer of bacteriochlorophyll a ; B_A and B_B , monomeric bacteriochlorophyll a molecules; H_A and H_B , bacteriopheophytin a molecules; Q_A and Q_B , ubiquinone molecules; Fe, iron ion. The arrow shows the electron path.

Purple bacteria export reducing equivalents in pair from the RC, and the molecule migrating from the RC to the other membrane proteins is the reduced quinol (QH₂).

Two electrons are needed to reduce the quinone to quinol, so, as the RC transfers electrons one by one, two quinones (Q_A and Q_B) are needed and act in a cycle in order to accumulate two reducing equivalents; after two RC turnovers a QH₂ is released from the Q_B site.

Q_A and Q_B have different features: Q_A is very tightly bound in its site and can be under the quinone and the free-radical anionic semiquinone form (Q_A^{•−}), while Q_B is reversibly bound and can be under the quinone, semiquinone, and quinol form within the cycle. What makes the main difference between Q_A and Q_B (that in some species are chemically identical – for instance, in *R. sphaeroides*) is the interaction with the protein in their binding sites.

The Q_A^{•−}/Q_A couple has a midpoint potential of about −180 mV. Then, the Q_A^{•−} migrates to the Q_B site and here the second electron reduces it to Q^{2−}. The protons are captured from the cytoplasm during the acceptor quinone cycle, and will be released in the periplasm by the cytochrome *bc*₁ complex to form the proton gradient needed for ATP synthesis. The overall reaction can be resumed as follows:

QH₂ is enough lipophilic to freely move throughout the membrane and transports its reducing power to different membrane-bound enzymes; in photosynthesis, it can reach not only the cytochrome *bc*₁ complex but also NADH dehydrogenase and succinate dehydrogenase, thus opening the cyclic photosynthetic process with the ‘reversed electron flow’. The reverse action of the NADH dehydrogenase is necessary to refurnish the cell of NADH.

Electron Acceptors and Donors Specific of Respiration Oxidases

Evidences have shown that purple bacteria can contain different types of terminal oxidases: some species (e.g., *R. sphaeroides*) contain the cytochrome *aa*₃ oxidase, the cytochrome *cbb*₃ oxidase, and a *bb*₃-type quinol oxidase; some other species (e.g., *R. capsulatus*) contain only the cytochrome *cbb*₃ oxidase and a *bb*₃-type quinol oxidase. In microorganisms that possess both cytochrome oxidases, the *aa*₃-type is predominant when the cells are grown aerobically, while the *cbb*₃-type is expressed mainly under microaerobic or photosynthetic conditions; otherwise, the *cbb*₃-type is the only cytochrome oxidase present.

All these proteins are part of the heme-copper oxidase (HCO) superfamily, but have significant differences in structure, in mechanisms, and in the quantity and quality of cofactors. For example, *aa*₃-type oxidases contain a binuclear copper cofactor named copper A (Cu_A), which is absent both in *cbb*₃-type and in quinol oxidases.

As Cyt *aa*₃ oxidase is not always present in purple bacteria, it is not discussed in this section.

Cytochrome *cbb*₃ oxidase

Cyt *cbb*₃ oxidase, a member of the HCO superfamily, is constituted by four subunits and contains many cofactors: two

Table 1 Hemes of the Cyt *cbb*₃ oxidase with their midpoint potentials (data refer to *Pseudomonas stutzeri* Cyt *cbb*₃ oxidase)

Redox center	Midpoint potentials (mV)
heme <i>b</i>	+310/+265
heme <i>b</i> ₃	+225
heme <i>c</i>	+245/+215
heme <i>c</i>	+245/+205
heme <i>c</i>	+185/+105

b-type hemes, three *c*-type hemes, and a copper B (Cu_B). Cyt *cbb*₃ oxidase passes electrons from the Cyt *c*₂ to O₂-pumping protons in the periplasm following the reaction:

Cyt *cbb*₃ oxidase is composed by a catalytic subunit containing the active site formed of a high-spin iron atom coordinated by a *b*₃ heme and a Cu_B. Electrons are transferred to the active site by a second, low-spin, *b*-type heme.

Electrons get to the catalytic subunit through a path created by rising potential *c*-type hemes: soluble Cyt *c*₂ binds close to the first *c*-type heme and the electron flows through and reaches the active site. Potentials have been measured for the five hemes of a Cyt *cbb*₃ oxidase of *Pseudomonas stutzeri*; in Table 1 those values are reported.

As already mentioned, this enzyme can be present at low levels during photosynthesis that in purple bacteria takes place under anaerobic conditions. This evidence suggested another enzymatic function, that is the reduction of substrates other than oxygen.

Quinol oxidase

Quinol oxidase operates in order to equilibrate the QH₂/Q ratio, oxidizing quinols to quinones as indicated in the following reaction:

The catalytic subunit is organized as in Cyt *cbb*₃ oxidase and the reaction mechanism is the same, but the difference stands in the absence of the *c*-type hemes.

This enzyme pumps protons in the periplasmic space but less efficiently than the *bc*₁–*cbb*₃ system, the reason for what this oxidase is mainly expressed under microaerophilic condition to avoid an overreduction of the quinone pool.

It was shown, in *R. capsulatus*, that Cyt *cbb*₃ oxidase is a low-O₂-affinity oxidase operating under conditions of high-O₂ concentration, while quinol oxidase is a high-O₂-affinity oxidase, operating under conditions of low-O₂ concentration. In this way, it is possible that all the available oxygen is used as an electron acceptor before switching to lower-yielding acceptors such as nitrate, dimethylsulfoxide (DMSO) or arsenate in the anaerobic respiration process.

Many purple photosynthetic bacteria are able to use electron acceptors other than oxygen: some conventional substrates such as sulfur and nitrogen compounds, and some exotic substrates such as DMSO, trimethylamine-*N*-oxide, and even arsenate and halogenated aromatics. All the enzymes

catalyzing these reactions contain complex cofactors, such as molybdoptertine, [FeS] clusters, tetraheme cytochromes.

Other Electron Acceptors and Donors

Hydrogen

Hydrogen can be an electron donor for purple bacteria, oxidized by a membrane-bound hydrogenase, which functions as a ubiquinone oxydoreductase. The below reaction can take place in both directions, depending on the presence or absence of the substrates.

However, H₂ can also be produced in purple bacteria by nitrogenase which not only functions primarily as nitrogen-fixing enzyme (eqn [8]), but also functions (in the absence of molecular N₂) using protons as electron acceptors (eqn [9]) to dissipate the excess of reducing power in the cell:

For these reasons, the hydrogenase and nitrogenase are often synthesized together and are regulated by complex and integrated signals.

Nitrogen Compounds

Purple bacteria can use oxidized nitrogen compounds as electron acceptors, carrying out denitrification. Many are complete denitrifiers, while some are so-called partial denitrifiers, because of the four enzymes required for the nitrate reduction to N₂ not all are ubiquitous. Generally speaking, purple bacteria contain most commonly the periplasmic nitrate reductase (Nap), the copper-containing nitrite reductase (Cu-Nir), the cytochrome *c* oxidase NO reductase (cNor), and the nitrous oxidoreductase (Nos); a few contain the membrane-bound nitrate reductase (Nar), and the heme-containing Nir (*cd*₁-Nir), but none contains the quinol-oxidizing Nor (qNor). Table 2 summarizes the steps of denitrification as it occurs in purple bacteria.

Taking into account the already-mentioned capability of reducing molecular nitrogen to ammonia, N₂ can be

Table 3 Differences in substrates and end products between purple sulfur and nonsulfur bacteria

	Most frequent substrates	Most frequent end products
Purple nonsulfur bacteria		
Alpha-proteobacteria	Sulfide, thiosulfate	Sulfate, elemental sulfur

<i>Chromatiaceae</i>	Sulfide, elemental sulfur, thiosulfate ^b , sulfite ^b	Sulfate

^aSulfur oxidation does not occur in phototrophic conditions; only in the presence of organic substrates.^bNot used by all *Chromatiaceae*.

considered an electron acceptor, even if the process has an assimilatory aim.

Sulfur Compounds

Many anoxygenic phototrophic purple bacteria use inorganic sulfur compounds as electron donors for reductive carbon dioxide fixation during photolithoautotrophic growth.

The behavior of sulfur and nonsulfur bacteria is slightly different, as indicated in Table 3.

Glossary

Cytochrome c_2 A heme-containing hydrophilic protein that functions as an electron carrier in both photosynthesis and respiration.

Photosynthetic reaction center A membrane-intrinsic protein complex that carries out the primary photochemical event, the charge-separation process.

Purple bacteria Prokaryotes that catalyze photosynthetic electron transfer. Divided into

Rhodospirillaceae (nonsulfur) and *Chromatiaceae* (sulfur).

Ubiquinone (formerly called coenzyme Q) A quinone derivative with a variable length side chain of isoprene units (mostly 8–10). It occurs in the lipid core of the eukaryotic inner mitochondrial membranes and of bacterial cytoplasmic membranes and functions as a mobile, lipophilic carrier of electrons (and protons).

Photosynthetic Reaction Centers

Virtually all life on Earth ultimately depends on the ability of photosynthetic organisms to convert solar energy into biochemically amenable energy. Photosynthesis is performed by higher plants, algae, and photosynthetic bacteria. Photosynthetic organisms absorb photons for the generation and storage of energy and for the production of biomass. A large proportion of photosynthetically active organisms consists of anoxygenic photosynthetic bacteria. In contrast to the higher plants, algae, and cyanobacteria of oxygenic photosynthesis, which contain the two membrane-bound photosystems (PS) I and II, each of the anoxygenic photosynthetic bacteria has only one type of reaction center (RC). Although the iron–sulfur type RCs of heliobacteria and anaerobic green sulfur bacteria resemble that of PSI, the pheophytin–quinone type RCs of purple bacteria are more similar to the RC of PSII.

Purple bacteria find their ecological niche in deeper layers of stagnant bodies of water. In all purple bacteria, the photosynthetic pigments and the photosynthetic apparatus are located within a more or less extended system of invaginated intracytoplasmic membranes. Unlike PSII, however, the purple bacterial RC is incapable of extracting electrons from water; instead, it must oxidize inorganic or organic molecules available in the environment. According to their electron-donor requirements, sulfur and nonsulfur purple bacteria have traditionally been distinguished. In contrast to sulfur purple bacteria (*Chromatiaceae*, *Ectothiorhodospira*), nonsulfur purple bacteria (*Rhodospirillaceae*) do not require inorganic sulfur compounds, such as hydrogen sulfide, but instead use organic electron donors such as malate or succinate as electron donors. Most of what is known today about purple bacterial RCs results from studies on RCs from nonsulfur purple bacteria. These are currently the best-characterized membrane protein complexes.

Subunit Composition and Molecular Characterization

Most purple bacterial RCs contain four protein subunits (Figure 1), referred to as H, M, L, and C (a tetraheme

cytochrome c). Some, however, such as the RCs of *Rhodobacter* (*Rb.*) *sphaeroides*, *Rb. capsulatus*, and *Rhodospirillum* (*Rs.*) *rubrum*, contain only the H, M, and L subunits. The related RC of the green aerobic thermophilic bacterium *Chloroflexus* (*Cf.*) *aurantiacus* lacks the H subunit.

Generally, RCs from purple bacteria have been isolated and characterized from *Rhodopseudomonas* (*Rp.*) *viridis* (suggested by Hiraishi in 1997 to be referred to as *Blastochloris viridis*), *Rb. sphaeroides*, *Rb. capsulatus*, and a number of other purple bacteria. Variant RCs have been created by site-directed mutagenesis as well as classical herbicide-resistance selection procedures and have been isolated and characterized from *Rb. capsulatus*, *Rb. sphaeroides*, and *Rp. viridis*.

RC preparations have a nonheme iron and four magnesium-containing bacteriochlorophyll cofactors per RC, as measured by atomic absorption spectroscopy. In *Rb. sphaeroides* and *Rp. viridis*, these are bacteriochlorophyll *a* and bacteriochlorophyll *b*, respectively (Figures 1(a) and 2(a)). Those preparations with a tightly bound C subunit have four iron-containing heme groups which are covalently bound to the protein via thioether bonds formed with the Cys residues of the heme attachment site sequences Cys–X–Y–Cys–His and the His is the fifth ligand to the heme iron. In the *Rp. viridis* RC, the sixth ligands to heme1, heme2, and heme3 are Met residues (His–Met-ligated hemes), whereas the sixth ligand to heme4 is a second His (*bis*-His ligation). Apart from these four hemes, all other cofactors are noncovalently bound by the L and M subunits. The six-coordinated nonheme ferrous iron is coordinated by the Nε atoms of four His residues and the two Oε atoms of a Glu residue. The fifth ligands to the five-coordinated bacteriochlorophyll–magnesium ions are provided by the Nε atoms of His side chains. In addition to these metal-containing cofactors, there are two bacteriopheophytin groups, a carotenoid, and two quinones bound by the RC. In *Rb. sphaeroides*, these are bacteriopheophytin *a*, spheroidene, and ubiquinone-10, respectively, whereas *Rp. viridis* contains bacteriopheophytin *b*, 1,2-dihydroneurosporene, menaquinone-9, and ubiquinone-9 (Figures 1(a) and 2(a)–2(c)).

Apart from the availability of high-resolution crystal structures discussed below, one major reason why, despite its

Figure 1 Structure and function of the photosynthetic RC. (a) Light-induced cyclic electron flow and the generation and utilization of a transmembrane electrochemical potential in the purple bacterium *Rp. viridis*. The structure of the *Rp. viridis* RC is represented schematically showing the heterotetramer of C, L, M, and H subunits as α traces in green, brown, blue, and purple, respectively, plus the 14 cofactors, which have been projected on to the molecule for better visibility. Also for the sake of clarity, the quinone tails are truncated after the first isoprenoid unit and the phytyl side chains of the bacteriochlorophyll and bacteriopheophytin molecules have been omitted, as have those atoms of the carotenoid molecule which were not observed in the electron density and assigned zero occupancy in the PDB entry 2PRC. Carbon, nitrogen, and oxygen atoms are drawn in yellow, blue, and red, respectively. (b) Equilibrium oxidation–reduction potentials of the *Rp. viridis* RC cofactors as compiled by Lancaster and Michel (see section Further Reading) as a function of intercofactor distance. The soluble electron donor protein cytochrome c_2 has been included as suggested in Figure 4(a). Reaction half-times indicated are taken from the references cited by Lancaster and Michel. The photochemical excitation is indicated by a dashed arrow and unphysiological charge recombination reactions are shown as dotted arrows. (c) Quinone reduction cycle. Reduced quinones are typeset in bold. Steps 2, 4, 5, and 6 are reversible (see text for details). (b) Reproduced from Lancaster CRD and Michel H (2001) Photosynthetic reaction centers. In: Messerschmidt A, Huber R, Poulos T, and Wiegardt K (eds.) *Handbook of Metalloproteins*, vol. 1, pp. 119–135. Chichester: Wiley, with permission from John Wiley & Sons.

Figure 2 Chemical structures of RC cofactors (a–c) and inhibitors at the Q_B site (d,e). (a) Bacteriochlorophyll *b*, as bound in the *Rp. viridis* RC. The bacteriochlorophyll *a* bound in the *Rb. sphaeroides* RC differs by the presence of a C8 ethyl group instead of the C8 ethylidene group indicated in red. Bacteriopheophytins (*a* or *b*) are the metal-free variants of the bacteriochlorophylls (*a* or *b*) with two protons bonded to the nitrogens of the unsaturated pyrrole rings A and C. (b) Menaquinone-*n*. The native Q_A in the *Rp. viridis* RC is menaquinone-9. (c) Ubiquinone-*n*. The native Q_A in the *Rp. viridis* RC is ubiquinone-9. In the *Rb. sphaeroides* RC, both Q_A and Q_B are ubiquinone-10. (d) Atrazine (2-chloro-4-ethylamino-6-isopropylamino-*s*-triazine). (e) Stigmatellin A.

complexity, the purple bacterial RC has become the ‘hydrogen atom of protein electron transfer’ (W W Parson), is the richness of its characterization by optical absorption, electron paramagnetic resonance, electron-nuclear double resonance, Fourier-transform infrared, resonance Raman, fluorescence, Stark effect, and other types of spectroscopy (see section [Further Reading](#) for detailed overviews).

X-Ray Crystal Structures of RCs from Purple Bacteria

The photosynthetic RC from *Rp. viridis* was the first membrane protein complex for which an atomic structural model could be determined by X-ray crystallography (Protein Data Bank (PDB) entry 1PRC). The structure of the four-subunit *Rp. viridis* RC is shown schematically in [Figure 1\(a\)](#). The structure of the

RC from *Rb. sphaeroides* (not shown) would appear almost identical except for the C subunit at the top, which would be missing. The more recently determined structure of the RC from the sulfur purple bacterium *Thermochromatium tepidum* (PDB entry 1EYS) is very similar in overall architecture to that of *Rp. viridis*.

The *Rp. viridis* RC has an overall length of 130 Å in the direction perpendicular to the membrane. Parallel to the membrane, the maximum width is about 70 Å. The central core of the RC is formed by the L subunit and the M subunit, which possess five membrane-spanning segments each. Both subunits are closely associated and noncovalently bind 10 cofactors as detailed above and shown in [Figure 1\(a\)](#). Large parts of the L and M subunits and their associated cofactors are related by a twofold axis of symmetry perpendicular to the plane of the membrane. The H subunit is anchored to the membrane by

a single membrane-spanning helix and is attached to the LM core on the cytoplasmic side. On the periplasmic side, the C subunit with its four covalently bound heme groups is attached. The N-terminal diacylglycerol moiety which, in addition to the interaction with the LM core, anchors the C subunit in the membrane is not visible in the electron-density map.

The pigments form two symmetry-related branches, also shown in **Figure 1(a)**, each consisting of two bacteriochlorophylls, one bacteriopheophytin, and one quinone, which both cross the membrane starting from the special pair D of two closely associated bacteriochlorophylls (D_M and D_L) near the periplasmic side, followed by the accessory bacteriochlorophyll, B, one bacteriopheophytin, ϕ , and a quinone, Q. As shown in **Figure 1(a)**, only the branch more closely associated with L subunit is used in the light-driven electron transfer. It is called the A-branch, the inactive one is the B-branch. The active branch ends with the primary quinone Q_A , the inactive one with the secondary quinone Q_B . Halfway between both quinones, the nonheme iron is located. The carotenoid is in van der Waals contact with B_B and disrupts the twofold symmetry. In both species, the crystallographic temperature factors, which are a measure for the rigidity of the structure, are considerably higher along the B-branch than along the A-branch.

Functional Aspects

Oxidation–Reduction Potentials

The oxidation–reduction midpoint potentials, E_M , of the four heme groups follow the order low, high, high, low in the sequence or low, high, low, high if the hemes are ordered with decreasing distance (see **Figure 1(b)**) from the primary electron donor D. Theoretical analysis by the application of continuum electrostatics to the crystal structure of the C subunit has provided quantitative estimations of the factors contributing to the equilibrium E_M values of the four hemes. Specific residues and the propionic side chains on the hemes are calculated to strongly modulate the E_M values. The correct division into low- and high-potential hemes can be obtained by taking only the protein into account. Consideration of heme–heme interactions is required to reproduce the experimental data quantitatively.

The redox potentials of the other *Rp. viridis* RC cofactors are also included in **Figure 1(b)**. The potential of the excited state D^* is derived from the free energy difference between the lowest vibrational levels of D and D^* . Estimated from the wavelength of the absorption maximum, the dimer of bacteriochlorophyll *b* in *Rp. viridis* provides an energy of 1240 meV between D and D^* , that of the bacteriochlorophyll *a* dimer in *Rb. sphaeroides* one of 1380 meV. The redox potential of *Rb. sphaeroides* D has been increased from 505 to 765 mV by the introduction of three additional hydrogen bonds to the special pair bacteriochlorophylls by site-directed mutagenesis, thus destabilizing the oxidized state of the donor, D^+ .

The redox potential of Q_A is higher in the *Rb. sphaeroides* RC than in the *Rp. viridis* RC because of the different chemical nature of the quinones (ubiquinone vs. menaquinone). However, it is still 67 mV lower than that of *Rb. sphaeroides* Q_B , even though both cofactors are chemically identical, thus requiring a role of the protein in tuning the *in situ* redox potentials of the quinones.

Kinetics

Figures 1(a) and **1(b)** show schemes of the electron-transfer steps that occur in the purple bacterial RC. Light absorption leads to an excited primary donor D^* , from which an electron is transferred via the monomeric bacteriochlorophyll B_A (reaction half-time: 2.8 ps) and the bacteriopheophytin ϕ_A (700 fs) to Q_A in 200 ps, leading to the formation of $D^+Q_A^-Q_B$. Rereduction of D^+ by cytochrome c_{559} (heme 3) occurs in 320 ns. These processes are much faster than the subsequent proton uptake and interquinone electron-transfer reactions. Therefore, the first step of quinone reduction in the RC can be viewed as a photochemical cytochrome oxidation, giving rise to the radical state $DQ_A^-Q_B$ (**Figure 1(c)**). Rereduction of cytochrome c_{559}^+ by cytochrome c_{556} (heme 2) occurs in 1.7 μ s. The second step of quinone reduction involves the transfer of the first electron to Q_B in 17–25 μ s, resulting in the state $DQ_AQ_B^-$. The one-electron reduction of Q_B is not associated with direct protonation and the semiquinone species is anionic. However, the $Q_A^-Q_B \rightleftharpoons Q_AQ_B^-$ equilibrium constant is pH dependent, as electron transfer is accompanied by substoichiometric proton uptake due to the protonation of amino acid residues. Cytochrome c_{556}^+ is rereduced by cytochrome c_2 in 40–60 μ s. In species that lack the C subunit, for example, *Rb. sphaeroides*, the photooxidized special pair is directly rereduced by cytochrome c_2 in a biphasic reaction. The fast phase of ~ 1 μ s is attributed to intermolecular electron transfer, the slow phase of 100 μ s is limited by docking and reorientation of the cytochrome c_2 -RC complex. After a second photochemical cytochrome oxidation, the diradical state $DQ_A^-Q_B^-$ is formed at rates similar to those for the first electron transfer. Coupled transfer of the first proton and the second electron to Q_B^- leads to the monoprotonated, doubly reduced state $DQ_A(Q_BH)^-$. Transfer of the second proton for the formation of Q_BH_2 is kinetically indistinguishable from the first proton transfer in the wild-type RC and can only be resolved in the case of mutants with significantly retarded second proton-transfer rates.

Functional Derivatives

Substrate Analog and Inhibitor Complexes

In the original *Rp. viridis* RC structure (PDB entry 1PRC), the Q_B site was poorly defined because it was only partially occupied with the native ubiquinone-9 in the standard RC crystals. However, ubiquinone-2-reconstitution experiments have yielded crystals with full quinone occupancy of the Q_B site. Subsequent X-ray diffraction analysis and refinement have led to a well-defined Q_B -site model (2PRC), with the quinone bound in the proximal position, that is, close to the nonheme iron (hydrogen-bonded to its ligand His L190, see **Figure 3(a)**). In the RC structure with a Q_B -depleted Q_B site (3PRC, **Figure 3(b)**), refined at 2.4 Å, apparently five, possibly six, water molecules are bound instead of the ubiquinone head group, and a detergent molecule binds in the region of the isoprenoid tail. Using the structures 2PRC and 3PRC as references, the original data set 1PRC was reexamined. A more quantitative analysis of the original data resulted in 20% of the Q_B sites being occupied with quinone in the proximal site,

Figure 3 Derivatives at the Q_B site of the *Rp. viridis* RC. (a) Comparison of distal (1PRC_{new}, cyan) and proximal (2PRC, yellow) ubiquinone-binding sites. (b) Comparison of Q_B-depleted (3PRC, pink) and ubiquinone-2-occupied (2PRC, yellow) Q_B sites. (c) Comparison of stigmatellin binding (4PRC, gray) and ubiquinone-2 binding (2PRC, yellow). (d) Atrazine binding (5PRC, pink) compared to distal (1PRC_{new}, cyan) and proximal (2PRC, yellow) ubiquinone-binding sites. (e) Mechanistic implications of the structures 2PRC, 3PRC, 4PRC, and the revised model 1PRC_{new} for the events at the Q_B site within the reduction cycle of quinone to quinol. The numbering of the steps is analogous to that in [Figure 1\(c\)](#). Hydrogen atoms are drawn as small light gray spheres. Dashed green arrows symbolize quinone movements.

30% having quinone bound in a more distal site, not hydrogen-bonded to His L190 and further away from the nonheme iron (see [Figure 3\(a\)](#)), and half of the Q_B sites being empty or having the quinone unaccounted for. A further structure, the RC complex with the inhibitor stigmatellin (see [Figure 2\(e\)](#)), refined at 2.4 Å, indicates that additional hydrogen bonds stabilize the binding of stigmatellin over that of ubiquinone-2 (4PRC, see [Figure 3\(c\)](#)). The binding pattern

observed for the stigmatellin complex can be viewed as a model for the stabilization of a monoprotonated reduced intermediate (Q_BH or Q_BH^+). This indicates that the Q_B site is not optimized for Q_B binding, but for Q_B reduction to the quinol. In combination with the results of electrostatic calculations, these crystal structures can provide models for intermediates in the reaction cycle of ubiquinone reduction to ubiquinol (**Figure 3(a)**), as discussed below.

The Q_B site is also a well-established site of herbicide action. Over half of the commercially available herbicides function by inhibition of higher plants at the Q_B site of the D1 polypeptide of the PSII RC. A commercially very important class of herbicides are the triazines, which were introduced by J R Geigy S A in the 1950s. A prominent example is atrazine ([Figure 2\(d\)](#)), first reported in 1957. According to statistics from 1995, atrazine was used on approximately 67% of all US corn acreage, 65% of sorghum acreage, and 90% of sugarcane acreage. Another well-known triazine is terbutryn (2-*t*-butylamino-4-ethylamino-6-methylthio-*s*-triazine). X-Ray crystal structures of complexes of the RC with atrazine (PDB entry 5PRC) and terbutryn (PDB entry 1DXR) have been determined at 2.35 and 2.00 Å resolution, respectively. In both cases, three hydrogen bonds bind the distal side of the inhibitors to the protein, and four additional hydrogen bonds, mediated by two tightly bound water molecules are apparent on the proximal side, as shown for atrazine in [Figure 3\(d\)](#). In contrast to the proximal binding of stigmatellin ([Figure 3\(c\)](#)), the triazine inhibitor partially overlaps with both the distal and the proximal ubiquinone-binding sites ([Figure 3\(d\)](#)).

Mutants

Work on site-directed mutagenesis of photosynthetic RCs started with the RC from *Rb. capsulatus*. This species is genetically very well characterized and able to grow non-photosynthetically under aerobic conditions, as well as under anaerobic conditions using, for example, dimethylsulfoxide as an electron acceptor. Most importantly, under these latter conditions, the photosynthetic apparatus is fully induced. Unfortunately, the RC from *Rb. capsulatus* could not be crystallized, thus thwarting proper inspection for structural changes.

The closely related *Rb. sphaeroides* can be grown under similar nonphotosynthetic conditions, so that site-directed mutagenesis is also straightforward. As mentioned above, this RC is amenable to inspection by X-ray crystallography for structural changes. Many amino acids that were considered to be of importance for pigment binding, electron transfer, or proton transfer were changed in *Rb. sphaeroides* RCs (see section [Further Reading](#) for detailed overviews). In addition to mutagenesis, quinone or bacteriochlorin cofactors may be removed or replaced chemically with a wide range of similar compounds.

Site-directed mutagenesis of the RC from *Rp. viridis* is possible, but more difficult. *Rp. viridis* can grow only under photosynthetic and, very slowly, under microaerophilic conditions. However, under microaerophilic conditions, the photosynthetic apparatus is hardly induced and photosynthetic growth conditions exert a selection pressure for revertants and suppressor mutants if the RCs are functionally impaired. On the other hand, very interesting herbicide-resistant mutants were obtained by classical selection procedures, with mutations some of which would not have been made by site-directed mutagenesis.

Some of these herbicide-resistant mutants of the *Rp. viridis* RC have also been analyzed by X-ray crystallography. For instance, the mutation Tyr L222 → Phe unexpectedly leads to resistance against the herbicide terbutryn. In the wild type, Tyr

L222 forms a hydrogen bond with the peptide carbonyl oxygen of Asp M43. As this hydrogen bond is now missing, a stretch of the M subunit (M25–50) moves into a new position. The side chain of Phe L222 rotates by 90° into the herbicide-binding site, thereby preventing the binding of terbutryn by steric hindrance, but at the same time introducing sensitivity to two other classes of PSII inhibitors normally inactive in bacterial RCs, the ureas and phenolics.

Using site-directed mutagenesis, the highly conserved Tyr L162, positioned halfway between D and the proximal heme3 (cytochrome *c*₅₅₉) in the *Rp. viridis* RC (see [Figure 4\(a\)](#), below), was exchanged against a number of amino acids. All mutants grew photosynthetically. The redox potentials of D and *c*₅₅₉ were changed by the mutations. The structures of two mutants (Tyr L162 → Phe and Tyr L162 → Thr) were determined and found not to differ significantly from the wild-type structure. Analysis of the kinetics of electron transfer led to the conclusion that the tyrosine residue at position L162 is not required for fast electron transfer from *c*₅₅₉ to D⁺.

A more recent mutation of Arg C264 → Lys decreases the midpoint potential of heme3 (cytochrome *c*₅₅₉) from +380 to +270 mV, that is, below that of heme2 (+320 mV, see [Figure 1\(b\)](#)). In the structure of the mutant RC at 2.46-Å resolution, no remarkable differences were found apart from the mutated residue itself. The half-time of electron transfer between heme2 and heme3 was the same as in the wild type, indicating that the observed reaction rate is limited by the very uphill electron transfer from heme2 to heme4 (see [Figure 1\(b\)](#)).

Inter- and Intramolecular Electron and Proton Transfer and Catalytic Mechanism

Intramolecular Electron Transfer

The kinetics of light-induced electron transfer via Q_A to Q_B and of the rereduction of the special pair have been detailed above. The reasons for the unidirectionality of electron transfer along the active A branch and not along the inactive B branch, despite the twofold pseudosymmetry of the LM core of the RC, have been the subject of numerous theoretical and experimental investigations. Slight differences in geometry, differences in rigidity, and differences in the amino acid composition of the L and M subunits have been suggested to contribute to unidirectionality. The latter aspect was specified by the theoretical identification of a large electrostatic field favoring charge separation along the A branch. A major contributor to the potential gradient is Arg L103, whose positive charge is stabilized by different sections of the polypeptide backbone. This dipolar stabilization leads to a much longer-range effect of the positive charge than if it were stabilized by a counterion.

An experimental observation consistent with this electrostatic analysis is the finding that a site-directed double mutant in *Rb. capsulatus* RCs (Leu L212 → His; Gly L201 → Asp) appears to show significant electron transfer to ϕ_B . The first mutation leads to the incorporation of the β bacteriochlorophyll in the ϕ_A position and the second mutation introduces a negative charge close to B_A, thus making electron transfer down the A branch less favorable.

Figure 4 Cytochrome c_2 oxidation by the photosynthetic RCs of *Rp. viridis* and *Rb. sphaeroides*. (a) Reduction of the photooxidized tetraheme C subunit of the *Rp. viridis* RC (color-coding as in Figure 1(a)) by *Rp. viridis* cytochrome c_2 (orange). Theoretical docking as suggested from mutagenesis experiments. (b) Reduction of the special pair D in the *Rb. sphaeroides* RC (color coding of the L, M, and H subunits analogous to Figure 1(a)) by *Rb. sphaeroides* cytochrome c_2 (orange) as determined by X-ray crystal structure analysis (PDB entry 1L9B).

Quinone Reduction and Protonation

Both Q_A and Q_B sites are deeply buried within the photosynthetic RC complex, approximately 15 Å from the cytoplasmic surface. Proton transfer to the reduced quinone within the Q_B site could occur by protons moving along a chain of proton donors and acceptors by a proton wire, or hydrogen-bonded chain mechanism. Possible proton donors and acceptors are protonatable amino acid residues and water molecules. A number of the protonatable residues between the Q_B site and the cytoplasmic surface have been shown to be functionally relevant to the proton-transfer process by analysis of site-directed mutations and second site revertants. The observed effects can be due to the modification of the kinetics and thermodynamics of electron or proton transfer. Electrostatic calculations based on the X-ray structure coordinates of the RCs from *Rb. sphaeroides* and *Rp. viridis* led to the identification of residues that can contribute to the changes in equilibrium distributions of protons in the different redox states of the protein, thus helping to determine the role of the functionally important residues.

In combination with the results of electrostatic calculations, the crystal structures 3PRC, 1PRC_{new}, 2PRC, and 4PRC discussed above (cf. Figures 3(a)–3(d)) can provide models for intermediates in the reaction cycle of ubiquinone reduction to ubiquinol (see Figure 3(e)). The binding of the incoming Q_B to the distal site displaces some of the water molecules present in the empty pocket. The quinone ring is flipped around the isoprenoid tail and further water molecules are displaced for the Q_B to occupy the proximal position (step 1a in Figure 3(e)). This is the position in which neutral Q_B accepts an electron from Q_A^- . The hydrogen bonds donated to the quinone will automatically lead to a tighter binding of the negatively charged semiquinone Q_B^- compared to the neutral Q_B (step 2). Additionally, the side chain of Ser L223 can reorient by rotation of its χ_2 ($C\alpha-C\beta-O\gamma-H\gamma$) torsional angle, thus establishing an additional hydrogen bond to Q_B^- . Coupled to the transfer of the second electron, the first proton

is transferred, possibly via a transiently protonated Ser L223 – OH_2^+ , thus forming the monoprotinated, doubly reduced intermediate Q_BH^- (steps 3 and 4). After transfer of the second proton (step 5), movement of the quinol from the proximal to the distal position (step 6a) may be facilitated by increased stacking interactions of the aromatic ring systems with the Phe L216 ring and the diffusion of water molecules back into the pocket. The structures of these intermediates provide explanations for their relative binding affinities, as required for proper enzymatic function of the Q_B site. A rearrangement of hydrogen bonds, most prominently the reorientation of the Ser L223 side chain for Q_B reduction, as suggested by the scenario in Figure 3(e), has also been calculated by Alexov and Gunner to be necessary to make Q_B reduction more favorable than Q_A reduction. These local rearrangements may constitute the conformational changes deduced to be required for function by a variety of experiments.

Cytochrome c_2 Oxidation

All four hemes of the *Rp. viridis* RC tetraheme C subunit are located close enough to the surface of the protein to accept electrons from soluble cytochrome c_2 . Site-directed mutagenesis in another nonsulfur purple bacterium, *Rubrivivax gelatinosus*, has led to the identification of a patch of acidic residues immediately surrounding the distal low-potential heme 1 of the tetraheme C subunit that apparently forms an electrostatically favorable binding site for soluble cytochromes. Thus, all four hemes in the C subunit appear to be directly involved in the electron transfer toward the photooxidized special pair. Based on these findings, a model was proposed for the transient cytochrome c_2 -RC complex for *Rp. viridis* (see Figure 4(a)).

In the case of the *Rb. sphaeroides* RC, which lacks the C subunit (cf. section Subunit Composition and Molecular Characterization), the photooxidized special pair D^+ is directly rereduced by cytochrome c_2 . The structure of the cocomplex of

the *Rb. sphaeroides* RC and cytochrome c_2 has been determined by X-ray crystallography at 2.4-Å resolution (cf. **Figure 4(b)**). In these crystals, D^+ is reduced by cytochrome c_2 at the same rate as measured in solution indicating that the structure of the complex in the region of electron transfer is the same in the crystal and in solution. The binding interface can be divided into two domains. The first domain contributes to the strength and specificity of cytochrome c_2 binding and is a short-range interaction domain that includes Tyr L162 (cf. **Figure 4(b)**), and groups exhibiting nonpolar interactions, hydrogen bonding, and a cation- π interaction. The second is a long-range, electrostatic interaction domain that contains complementary charges on the RC and cytochrome c_2 . In addition to contributing to the binding, this domain may help steer the unbound proteins into the right orientation.

Relevance to PSII

Based on the determined structure of the purple bacterial RC, very specific sequence homologies, and azidoatrazine labeling, the RC core of higher plant PSII was proposed to be similar to the LM core of the bacterial RC, with the D1 and D2 proteins corresponding to the L and M subunits, respectively. This proposal could be verified experimentally. Recently, suitably designed, modified bacterial RCs have been shown to mimic tyrosine oxidation in PS II.

Glossary

Aldol-type reaction Biochemical reactions related in their chemical mechanisms to the classical aldol condensation and cleavage reactions of organic chemistry.

Coenzymes Small organic molecules that function together with enzymes to catalyze specific types of chemical reactions.

Lysine unit A lysine residue, a molecule of the amino acid lysine incorporated into a protein molecule.

Substrate The substance which undergoes the reaction catalyzed by an enzyme.

Tetrahydrofolic acid A coenzyme formed by reduction of the vitamin folic acid.

Pyridoxal phosphate (PLP) is one of several small organic molecules known as coenzymes, compounds that are essential to all forms of life. Coenzymes provide chemical functionality to enzymes that the 20 proteinogenic amino acids cannot. PLP is employed by a large number of enzymes. The majority of these are involved in primary metabolism, in pathways for the synthesis or degradation of amino acids or other nitrogen-containing compounds. In free living microorganisms such as the common *Escherichia coli* laboratory bacterium, approximately 1.5% of the total genes encode PLP-dependent enzymes. The Enzyme Commission has cataloged more than 150 distinct catalytic activities that are PLP dependent. Thus, PLP-dependent enzymes are central to the nitrogen metabolism of all living systems.

Vitamin B₆ constitutes a family of chemical structures, as shown in Figure 1. PLP, the most common enzymatically active form of vitamin B₆, is the phosphoric acid ester of pyridoxal. It is synthesized by plants and by many microorganisms, but humans must obtain it (or the other forms) from dietary sources. The major form of vitamin B₆ in plants (and in vitamin pills) is the alcohol pyridoxol (pyridoxine). In tissues of our bodies (as well as of other organisms), this is converted to pyridoxol 5'-phosphate, which is oxidized to the aldehyde PLP (Figure 1). Some enzymes can convert PLP reversibly to pyridoxamine phosphate (PMP) by a process known as 'transamination' (Figure 2). All organisms contain PLP and PMP, most of which is bound to enzymes.

Transamination

Transamination is the most common reaction type catalyzed by PLP-dependent enzymes. It is a biologically important process by which living cells reversibly transfer the amino group from an amine (e.g., γ -aminobutyrate) or α -amino acid (e.g., aspartate) to an α -keto carboxylic acid (e.g., α -ketoglutarate). (Figure 2). In the human body, aminotransferases catalyze many different steps in pathways for the biosynthesis and breakdown of amino acids. For example, glutamic acid can donate nitrogen to α -keto acids to form amino acids such as alanine and aspartic acid.

The process occurs via two half reactions. In the first, the amino group is transferred from the amine or amino acid

to PLP to form PMP. In the second, the amino group from PMP is transferred to the α -keto acid (Figure 2). During the reactions, PLP and PMP are held tightly in the active sites of the enzymes. Transamination proceeds through covalent substrate-coenzyme intermediates known as 'aldimines' (Figure 3) and 'ketimines'. Formation of the covalent external aldimine between the substrate and PLP allows the electrophilic pyridine ring to stabilize, by resonance, carbanionic intermediates formed on the substrates.

The Variety of PLP-Dependent Reactions

Transamination is only one of many reactions of amino acids and amines that are catalyzed by PLP-dependent enzymes. Some of these are listed in Table 1. Groups *a*, *b*, and *c* in this table are defined by the cleavage of one of three possible bonds to C α of the external aldimine intermediate. The enzymes in group *a*, which includes transaminases, initiate reaction by removing a proton from C α of the substrate. In doing so, these enzymes form a carbanionic, 'quinonoid' intermediate (Figure 4). For several enzymes, this intermediate has been identified spectroscopically. The quinonoid intermediate reacts in different ways, depending on the reaction being catalyzed. Aminotransferases catalyze addition of a proton to the exocyclic carbon of PLP at the 4 position of the pyridine ring, leading to a ketimine intermediate. Overall, this is a 1,3-prototropic shift of a hydrogen. Subsequent hydrolysis of the ketimine intermediate yields the PMP form of the enzyme and the α -keto acid product. The transamination cycle is completed by a second α -keto acid reacting with the PMP enzyme through the reverse of the above sequence of steps.

Racemases, which remove a proton from C α of the external aldimine, add a proton back to the same carbon atom but from the opposite side of the planar quinonoid intermediate (Figure 4). The effect is to catalyze the interconversion of two stereoisomers known as the L- and D-forms of the amino acid. Bacteria form D-alanine from L-alanine using PLP-dependent alanine racemase. They utilize the D-alanine, as well as D-glutamic acid, in their cell walls. The D-amino acids provide protection from extracellular proteases that act on L-amino acids. Small amounts of D-serine are found in the human brain. It is formed

from L-serine by a PLP-dependent racemase that is structurally distinct from alanine racemase.

A third type of reaction of quinonoid intermediates (Figure 3) is nucleophilic addition to a carbon, which occurs

in the biosynthesis of the cyclic amino acid aminocyclopropane carboxylic acid, a precursor to the plant hormone ethylene, from S-adenosylmethionine.

A large group of enzymes catalyzes a fourth type of reaction, which involves elimination of a leaving group such as $-OH$ or $-SH$. This may be followed by nonenzymatic decomposition of the product with liberation of NH_3 and other products, or replacement of the leaving group by a new group. These reactions play many roles in both the biosynthesis and degradation of amino acids. A familiar example of such a decomposition reaction initiates the release of compounds giving the characteristic odor to crushed garlic.

A second major group of PLP-dependent enzymes, the decarboxylases, removes CO_2 from the substrate. These enzymes also function in both catabolic and biosynthetic pathways. In each case, the irreversible loss of CO_2 drives the pathway in the needed direction. The most common decarboxylases participate in the formation of neurotransmitters such as γ -aminobutyrate, dopamine, adrenaline, and serotonin.

A third major group of PLP-dependent enzymes catalyzes cleavage or formation of carbon-carbon bonds in amino acids. These reactions resemble aldol-type reactions of organic chemistry. An example is formation of serine from glycine and formaldehyde. The latter, being a toxic compound, is carried as a derivative of another coenzyme, tetrahydrofolic acid. The enzyme serine hydroxymethyltransferase (Table 1), which catalyzes this reaction, allows bacteria and plants to form serine from glycine and also allows mammals to form glycine from serine.

A fourth, large group of enzymes (d in Table 1) have more complex mechanisms. Examples include the decarboxylation of the β carbon of aspartate, cyclopropyl ring opening of aminocyclopropanecarboxylate, radical-dependent reactions, etc. One of these is a bacterial enzyme that converts the selenium-containing selenocysteine into L-alanine and elemental selenium (Se^0). Related enzymes in all organisms transfer sulfur, as S^0 , into important metal-sulfur clusters such as Fe_4S_4 or the $MoFe_7S_9$ cluster, which participates in conversion of N_2 to HN_3 by nitrogen-fixing bacteria.

Figure 4 The formation of the carbanionic quinonoid intermediate is thought to be central to the reaction mechanisms of most PLP enzymes. It has a variety of fates, according to reaction type. In transamination, for example, it is protonated on C4' of PLP to give a ketimine intermediate that is hydrolyzed to the PMP enzyme form and a keto-containing product.

Chemical Mechanisms

The basic mechanistic steps are shown in [Figures 3](#) and [4](#); however, several steps are not shown for simplicity. Many individual chemical steps must occur in sequence for each reaction catalyzed, and PLP-dependent enzymes do a remarkable job of ensuring high fidelity given the complexity of the reactions they catalyze. In a few cases, such as with aspartate aminotransferase, the mechanistic details have been well characterized by use of spectroscopic techniques and by the determination of high-resolution structures by X-ray crystallography.

In the resting enzyme, PLP makes a Schiff base linkage to the ε -NH₂ group of lysine in the protein structure, which is called the 'internal aldimine'. Substrate binding often induces a conformational change in the protein, commonly leading to an enzyme-substrate complex in which the substrate is shielded from solvent. The first chemical step in all PLP-dependent reactions is the formation of a Schiff base with the substrate (external aldimine) via attack of the substrate amino group on the internal aldimine. It is from the external aldimine that the different reaction types diverge (i.e., the external aldimine is the only common intermediate for all PLP-dependent enzymes).

The lysine ε -NH₂ group that is freed from the internal aldimine can serve as a catalytic base that removes protons from the substrate in subsequent steps. In aminotransferases, for example, lysine 258 removes the proton at C α of the substrate and places it on C4' of PLP to form a ketimine. The structures, chemical groups involved, and individual steps vary from one enzyme to another and one reaction type to another. Most PLP-dependent reactions do not form PMP as an intermediate. However, virtually all PLP-dependent enzymes make use of an active site lysine as a general acid/base catalyst for multiple proton transfers.

The fundamental importance of the ring nitrogen at the bottom of the structure in [Figure 3](#) lies in its action as an electron-withdrawing group. In many PLP-dependent enzymes, a negatively charged carboxylate side chain forms a hydrogen bond to the N⁺-H at the bottom of the PLP ring. This carboxylate helps, through electrostatic interactions, to keep the ring protonated. On the other hand, the 3'-phenolate group opposes electron withdrawal from the substrate, perhaps assisting in other steps in the reaction such as interconversion

of internal and external aldimines. The 3'-phenolate group also helps to hold a proton on the Schiff base nitrogen as shown in [Figure 3](#).

In 1966, Dunathan proposed that the primary event in determining reaction specificity, cleaving the appropriate bond to C α of the external aldimine intermediate, is controlled by stereoelectronic effects. In other words, when a bond to C α is aligned parallel to the *p* orbitals of the conjugated aldimine/pyridine ring structure, that bond is more easily broken. This is so because the negative charge that develops during the bond-breaking process will be stabilized by resonance. Each enzyme must hold its substrate in such a way that the appropriate bond to the C α atom is parallel to the *p* orbitals of the conjugated π system. Thus, binding interactions between the enzyme and substrate are especially critical in maintaining reaction specificity in PLP-dependent enzymes.

Pyrimidine Biosynthesis and Degradation (Catabolism)

M Löffler and E Zameitat, Philipps-University, Marburg, Germany

© 2013 Elsevier Inc. All rights reserved.

Glossary

Antipyrinimidine A structural analog that is taken up by cells and interferes with normal metabolism. In a broad sense, drugs which reduce the production of pyrimidine nucleotides.

Flavoenzyme Enzyme containing a flavin group as redox cofactor.

Metabolon Physically associated enzymes of a metabolic pathway to facilitate substrate channeling.

Nucleoside Consists of [1 base+1 (deoxy)ribose] such as uridine.

Nucleotide Consists of [1 base+1 (deoxy)ribose+1–3 phosphate groups] such as deoxythymidine triphosphate (dTTP) or NTP (nucleoside triphosphate; N, base not specified).

Salvage Recycling of preformed nucleosides by cells.

De Novo Synthesis

Formation of Uridine Monophosphate

Chemically, pyrimidines are heterocyclic six-membered ring structures containing two nitrogen atoms. The pyrimidine bases of nucleic acids possess an amino or hydroxyl group at position 4, and always an oxygen function at position 2. Thymine, in addition, has a methyl group at position 5. This gives rise to tautomeric structures for the bases uracil, cytosine, and thymine. The first pyrimidine nucleotide in cells, uridine monophosphate (UMP), is synthesized from CO₂, the glutamine amide group, aspartate, and phosphoribosyl-1-pyrophosphate (PRPP) (Figures 1 and 2). In contrast to the biosynthesis of purine nucleotides, the pyrimidine ring is assembled first and then linked to ribose phosphate to form a pyrimidine nucleotide. In higher eukaryotes, the cytosolic enzyme catalyzing formation of carbamoyl phosphate, carbamoylphosphate synthetase II (CPSase II) (Figures 2 and 1, no. 1), is distinctly different from carbamoylphosphate synthetase I, which is found in mitochondria as the first reaction of arginine biosynthesis and urea cycle in mammalian liver, and thus CPSase II is the first step committed to pyrimidine metabolism in higher animals. The cleavage of two adenosine triphosphate (ATP) is required to form the high-energy-phosphate bond of carbamoyl phosphate. The formation of *N*-carbamoylaspartate (aspartate transcarbamoylase (ATCase), no. 2) is the committed step for pyrimidine synthesis in prokaryotes. Next, the pyrimidine ring is cyclized on dehydration by dihydroorotase (DHOase, no. 3). In higher animals, the first three enzymes together with glutaminase (which provides the amino group from the side-chain amide group of glutamine) have been fused together (exon shuffling) during evolution to form a single polypeptide, CAD (CPSaseII + ATCase + DHOase). This protein is located mainly in the cytosol and to some extent in the nucleus. Plants, such as prokaryotes, possess these enzymes individually encoded and located in chloroplasts. Formation of orotate from dihydroorotate is catalyzed by the mitochondrial flavoenzyme dihydroorotate dehydrogenase (DHODH, no. 4) transferring the reducing equivalents to the proximal acceptor ubiquinone (Q, Figure 2) and final acceptor molecular oxygen in the

respiratory chain. Thus, the energy of dihydroorotate oxidation can be stored in ATP. Orotate phosphoribosyltransferase (OPRTase, no. 5) and orotidine decarboxylase (ODCase, no. 6) are fused on one bifunctional polypeptide, UMP synthase, operating in the cytosol of higher eukaryotes except in plants. Thus, only three genes (chromosomal location in Man: 2p21(CAD), 16q22 (DHODH), and 3q13 (UMP synthase)) code for the enzymes catalyzing the reaction of *de novo* UMP synthesis.

Regulation

Pyrimidine *de novo* synthesis is a demonstration that compartmentation within different parts of the cell – cytosol, mitochondria, and chloroplasts – enhances the mode of regulation and flexibility of a metabolic pathway. Because of gene duplication, eukaryotes now have the potential to compartmentalize the synthesis of carbamoylphosphate for either pyrimidines (cytosol), or arginine and urea (mitochondria). In humans, urea synthesis takes place only in the liver. The location of DHODH (Figure 2) in the inner mitochondrial membrane and its connection to the functional respiratory chain ensures the most efficient oxidation of dihydroorotate in aerobes. In turn, pyrimidine biosynthesis becomes a pacemaker for cell growth and proliferation under limited oxygen tension. Patients with acquired or inherited defects in mitochondria energetics, however, may suffer from a concomitant pyrimidine nucleotide starvation or imbalance. The two multienzyme polypeptides (CAD and UMP synthase) achieve a micro-compartmentation of pyrimidine *de novo* synthesis. Encoding five enzyme activities on two polypeptides simplifies the coordination and regulation of gene expression and activity. In addition, the direct transfer of a product from one active site to the next enzyme (channeling) considerably increases the efficiency of pyrimidine biosynthesis in higher eukaryotes. Evidence for the location of CAD and UMP synthase close to the mitochondria surface has been obtained in an electron microscopic study. A metabolon-like complex facilitating the movement of substrate and product between cytosol and mitochondrion would allow a rapid increase in *de novo* synthesis when needed. The molecular regulation of pyrimidine *de novo* synthesis occurs at step 1

Figure 1 Biosynthesis, interconversion and degradation of pyrimidine nucleotides. The enzymes (given by numbers in the scheme) perform the *de novo* synthesis (1–6, go to [Figure 2](#)), interconversion of UMP to other ribonucleotides and deoxyribonucleotides (7–13), the salvage of preformed metabolites from dietary products or catabolism of nucleic acids (14–18), the first steps of catabolism (19–20) and the degradation (21–23, explained in [Figure 4](#)): 1, carbamoyl phosphate synthetase; 2, aspartate transcarbamoylase; 3, dihydroorotate dehydrogenase; 4, dihydroorotate dehydrogenase; 5, orotate phosphoribosyltransferase; 6, orotidine 5′-monophosphate decarboxylase; 7, uridine(pyrimidine) monophosphate kinases; 8, pyrimidine diphosphate kinases; 9, thymidine monophosphate kinase; 10, cytidine triphosphate synthetase; 11, ribonucleoside diphosphate reductase; 12, dUDP phosphohydrolase; 13, thymidylate synthase; 14, uridine/cytidine kinase; 15, thymidine kinase; 16, deoxycytidine/deoxyuridine kinase; 17, pyrimidine 5′-nucleotidases; 18, (deoxy)cytidine deaminase; 19, uridine phosphorylase; 20, thymidine phosphorylase; 21, dihydropyrimidine dehydrogenase; 22, dihydropyrimidinase; 23, ureidopropionase. → (pyro)phosphohydrolases, not specified here; 5*, uptake of 5-fluorouracil by orotate phosphoribosyl transferase in malignant cells.

of CAD. The CPSase II specific activity is low relative to that of the subsequent enzymes. It is allosterically activated by PRPP and feedback inhibited by uridine triphosphate (UTP). The CAD activity is tuned by phosphorylation at two sites: mitogen-activated protein (MAP) kinase action leads to more easily activated enzyme by reducing the efficacy of UTP and increasing that of PRPP, and phosphorylation at a second site by the cyclic adenosine monophosphate (cAMP)-dependent protein kinase A leads to a more easily inhibited enzyme. Hence, by losing feedback inhibition, carbamoyl phosphate synthesis is activated rapidly and sensitively in response to external growth-promoting signals. At the end of S-phase of the cell cycle, the inhibition by UTP is more pronounced, and the activation by PRPP is reduced. A modulation of ATCase activity is assured by a cooperative binding of carbamoyl phosphate and aspartate. An overflow into pyrimidine biosynthesis can occur from overabundant carbamoyl phosphate production in the case of urea cycle defects in liver: the carbamoyl phosphate leaves the mitochondria

and is used by the ATCase of CAD. Under these conditions, UMP synthase is the limiting enzyme, presumably because of an insufficient supply of PRPP for orotidine monophosphate (OMP) synthesis, causing orotate to accumulate and to be excreted (secondary orotic aciduria).

Deficiency and Interference

The only hereditary but rare defect of pyrimidine *de novo* synthesis diagnosed for certain in living humans is that of UMP synthase (orotate phosphoribosyltransferase (OPRT) domain or orotidine decarboxylase (ODC) domain) with different clinical manifestations, such as anemia or megaloblastic changes in bone marrow, immunodeficiency and gross orotate excretion in type 1 deficiency or orotidine plus orotic acid excretion, neurological deficits, and intellectual impairment in type 2 deficiency. Only recently, by exome sequencing, the presence of DHODH gene mutations was identified as a putative cause for a rare malformation disorder

Figure 2 Compartmentation of pyrimidine *de novo* synthesis. In higher eukaryotes the multifunctional enzyme CAD (CPSase 2 + ATCase + DHOase, no. 1 + 2 + 3) and UMP synthase (OPRTase+ODCase, no. 5 + 6) are cytosolic, the monofunctional DHODH (no. 4) is in mitochondria and connected via ubiquinone (Q/QH₂) to the functional respiratory chain at the stage of complex III (III). Electrons are transferred to oxygen via cytochrome oxidase (IV). ATP synthetase (V). Note that in plants, no. 1, 2, 3 and no. 5 + 6 are in chloroplasts. In Gram-positive bacteria and anaerobic yeasts, all enzymes are cytosolic. In Gram-negative bacteria, the quinone-dependent DHODH is attached to the plasma membrane; in many parasites, it is located in mitochondria.

named 'Miller syndrome'. Such new strategies of genetic analyses will guide concerted diagnostics – which have been greatly improved for the detection of intermediates of pyrimidine metabolism in body fluids through tandem mass spectrometry – rather than wide-screening protocols for inborn errors of metabolism. A hereditary defect of the CAD enzyme is not known to date.

There are no specific inhibitors of CPSase of chemotherapeutic interest. *N*-Phosphonoacetyl-L-aspartate (PALA), a model inhibitor of ATCase in prokaryotes, was clinically disappointing because gene amplification leading to overproduction of CAD caused resistance of human cancer cells. Since parasites such as *Plasmodium* or *Toxoplasma* synthesize pyrimidine nucleotides via the *de novo* pathway only – unlike purine nucleotides which are synthesized via a salvage pathway – quite a lot of efforts have been made to solve the three-dimensional structure of these enzymes with the rationale to develop potent inhibitors of utmost specificity against these and other parasites. The drug design for DHOase inhibitors focuses on its thiol Zn²⁺ center.

Antimetabolites of UMP synthase with anticancer activity but limited by toxicity at high dosage to patients (e.g., 6-azauracil and pyrazofurin) have been shown to suppress reproduction of *Toxoplasma gondii* and *Plasmodium falciparum*. Some widely used drugs, for example, the calcium channel blockers nifedipine and nimodipine, were shown to suppress murine OMP decarboxylase and uridine kinase, comparable to barbituric acid as orotidine analog if it is converted to barbiturate ribonucleotide. Natural and chemical ubiquinone analogs, potent inhibitors against DHODH, failed to get clinical approval as anticancer drugs. Severe impairment of other ubiquinone-binding enzymes was assumed. The naphthoquinone atovaquone, a competitor for ubiquinone-dependent reactions in parasites, has been applied for treatment of opportunistic infections and malaria. The inhibition of DHODH by the isoxazol leflunomide, which was licensed in 2000, is central to the efficacy of this drug in treating rheumatoid arthritis and other autoimmune diseases. The present concept to find new drugs for the modulation of pyrimidine nucleotide pools in immune cells is concentrated on DHODH.

Interconversions in Pyrimidine Biosynthesis

Formation of Cytidine and Thymidine Nucleotides

Pyrimidine nucleoside di- and triphosphates are produced by ATP-dependent kinases (Figure 1, no. 7–9). Cytidine triphosphate (CTP) synthase (no. 10) catalyzes the formation of CTP from UTP using the amide group of glutamine in an ATP-dependent reaction (Figure 3(a)). Only at the time

of DNA replication, the deoxynucleotide pools increase noticeably. Nucleoside 5'-diphosphate reductase (ribonucleotide reductase, no. 11) catalyzes the formation of deoxyribose (exchange of H for OH at C2') of pyrimidine as well as purine ribonucleotides using dicysteinyl proteins of the thioredoxin/glutaredoxin superfamily of small redox proteins with final nicotinate adenine dinucleotide phosphate, reduced form (NADPH) as hydrogen donor (Figure 3(b)).

Figure 3 Formation of cytidine and thymidine nucleotides. (a) The synthesis of CTP from UTP by CTP synthetase. (b) Conversion of UMP to dUMP by ribonucleotide reductase, schematic presentation of the enzyme with affiliated glutaredoxin (Grx) and glutathione (GSH/GSSG) reductase catalyzed reactions. (c) The thymidylate synthase catalyzed reaction and regeneration of methylenetetrahydrofolic acid (THF) by means of dihydrofolate reductase.

The product deoxyuridine diphosphate (dUDP) is dephosphorylated to deoxyuridine monophosphate (dUMP) (no. 12). In case of deoxyuridine triphosphate (dUTP) formation, this can effectively be reconverted to dUMP by the deoxyuridine triphosphate nucleotidohydrolase (pyrophosphohydrolase, [Figure 1](#)) in order to prevent its incorporation into DNA. dUMP is used by thymidylate synthase (no. 13) to form deoxythymidine monophosphate (dTMP) by means of (N^5 , N^{10} -) methylenetetrahydrofolic acid (THF) as a one-carbon donor and reducing agent ([Figure 3\(c\)](#)).

Regulation

The enzymes of this part of pyrimidine synthesis are cytosolic. Their activity is strictly controlled by availability of substrates or by their products and other ribonucleotides and deoxyribonucleotides, respectively. This is a well-understood mechanism to ensure well-balanced pools of pyrimidine and purine (deoxy)ribonucleotides in cells. For example, CTP is a negative effector and the purine nucleotide guanosine triphosphate (GTP) is an activator of CTP synthetase, which catalyzes the rate-limiting step in the synthesis of cytidine nucleotides. This enzyme and CAD were described to be associated with the cytoskeleton, hence are able to move around according to change in cell shape. Ribonucleotide reductase (no. 11) of all eukaryotes and some bacteria consists of two nonidentical protein subunits, one containing the substrate-binding site and different effector-binding sites, the other a stable tyrosyl radical generated by the reaction of molecular oxygen at a nonheme binuclear iron center. This reaction gives the second control point for nucleic acid synthesis by O_2 in aerobes. Anaerobes have simpler monomeric or dimeric structures with different metal or coenzyme B12 centers. The key event in all ribonucleotide reductase proteins is the initiation of a transient thiyl radical at the substrate site by means of the radical at the second subunit. In eukaryotes, this enzyme is subject to a sophisticated control mechanism, in which an excess of one deoxyribonucleotide inhibits reduction of all other ribonucleotides. Effective inhibition by deoxyadenosine triphosphate (dATP) or deoxythymidine triphosphate (dTTP) explains the intrinsic toxicity of elevated levels of deoxyadenosine and thymidine to many organisms and also the immunodeficiency in patients with adenosine deaminase and purine nucleoside phosphorylase deficiency. ATP is the main activator of ribonucleotide reductase, and deoxycytidine triphosphate (dCTP) and dTTP are major positive or negative effectors for the interconversion and salvage of deoxyribonucleosides. The key regulatory mechanism for thymidylate synthase is the delivery of THF by dihydrofolate reductase ([Figure 3\(c\)](#)). In plants and parasitic protozoa, this enzyme is fused as a bifunctional polypeptide with thymidylate synthase.

Deficiency and Interference

Effective inhibitors of ribonucleotide reductase (e.g., the radical scavenger hydroxyurea, HU) are potent inhibitors of DNA synthesis and hence of replication. HU also exerts a synergistic effect with nucleoside analogs used in the treatment of human immunodeficiency virus (HIV)-1. This is attributed to reduction in intracellular deoxyribonucleotides coupled with interference

in antigen-dependent T-lymphocyte activation. However, the clinical application is disputed. It is noteworthy that healthy human lymphocytes do not pick up exogenous orotic acid, nor do they convert UTP to CTP. However, both these pathways are upregulated in malignancy. Most of the CTP synthetase inhibitors that have been developed and tested with experimental tumors are synthetic pyrimidine analogs (e.g., deazauridine and cyclopentenyl cytosine). Since some protozoan parasites have limited capacity for CTP formation, the application of CTP synthetase inhibitors was suggested for the treatment of sleeping sickness. Thymidylate synthase and dihydrofolate reductase are well-established target enzymes in cancer therapy using 5-fluorouracil and folate analogs (e.g., methotrexate) preventing THF regeneration. In cancer cells, the drug 5-fluorouracil can be activated to 5-F-UMP by OPRFase with PRPP (no. 5) or by uridine phosphorylase with ribose-1-phosphate (no. 9, in a reverse reaction).

Salvage

Phosphorylation and Dephosphorylation

The fact that hereditary orotic aciduria does respond to life-long supply with uridine but not to uracil indicated that pyrimidine nucleoside salvage can compensate for the lack of *de novo* synthesis in humans, if the dosage as food additive is in grams per day and increasing from childhood to adulthood. This is in direct contrast to purines where the gut mucosa contains a complement of enzymes which degrades all dietary purines to the end product, uric acid. Prominent salvage capacity is expressed in lymphoid cells, polymorphonuclear cells, and the central nervous system. Uridine, (deoxy)cytidine, and thymidine originating from daily nutrients or intracellular breakdown from nucleic acids are rescued from circulation by cytosolic (deoxy)ribonucleoside kinases that show a high level of specificity with respect to the base and sugar moieties, with ATP as the major phosphate donor (no. 14–16). In contrast to purines, the salvage of free pyrimidine bases at the expense of PRPP does not occur in mammalian tissue. Orotate as a natural component of dairy food is taken up and converted to UMP only by liver and erythrocytes. It can also stem from food additives such as zinc orotate and magnesium orotate, which are used for metal ion substitution therapy. Salvage of deoxycytidine is important in DNA repair. Deoxycytidine kinase is also responsible for activating some nucleoside analogs as well as natural deoxyribonucleosides – such as deoxyadenosine in adenosine deaminase deficiency. Pyrimidine and purine deoxyribonucleoside kinases seem to have evolved from a common progenitor multisubstrate kinase. Multisubstrate deoxyribonucleoside kinases were found in several insect species and shown to phosphorylate pyrimidines as well as purine (deoxy)nucleosides with high efficiency. The dephosphorylation of pyrimidine (deoxy)ribonucleoside monophosphates is catalyzed by 5'-nucleotidases (no. 17) which are expressed as specific isoforms in different tissues. This reaction is a prerequisite for transport and delivery of pyrimidines by the circulation. In cells, uridine and deoxyuridine can also be formed from cytidine and deoxycytidine by cytidine deaminase (no. 18).

Regulation

The balance between excretion and uptake is set by intracellular substrate cycles involving 5'-nucleotidases, kinases, and nucleoside transport through the plasma membrane of cells. Uridine is taken up effectively by a carrier-mediated concentrated transport process or by cotransport, by all human cells except erythrocytes.

Deficiency and Interference

Different mutants of the pyrimidine-5'-nucleotidase (no. 17) are known to cause enzyme deficiency. This is inherited as an autosomal recessive trait. The symptoms include nonspherocytic hemolytic anemia, splenomegaly, and hepatomegaly; gross elevations in erythrocyte UTP/CTP are characteristic findings. A different (acquired) deficiency of 5'-nucleotidase associated with hemolytic anemia has been described in patients with lead poisoning or thalassemia. Uridine 5'-nucleotidase superactivity was described to include developmental delay, recurrent infections, and hyperactivity of children. Daily treatment with uridine resulted in a remarkable improvement of the clinical condition, as was the case with hereditary orotic aciduria patients. Mutations in the gene of thymidine phosphorylase (no. 20) caused mitochondrial neurogastrointestinal encephalomyopathy in humans. Patients with mutations in the mitochondria-specific thymidine kinase-2 develop myopathy and depletion of muscular mitochondrial DNA. Pyrimidine (deoxy)ribonucleoside kinases are critical constituents for

interference by pharmacological agents; they are of key importance for the channeling of nucleoside analogs (such as arabinosyl cytosine, azidothymidine, and 2'/3'-dideoxycytidine) in cell metabolism of humans and pathogens. On the other hand, strategies for inhibition of pyrimidine biosynthesis by drugs can be anticipated in cells with high activities in the salvage reactions. This aspect underlies current research on structure and function of pyrimidine (deoxy)ribonucleoside transporters in the plasma and mitochondria membranes and their connection with salvage and biosynthesis of pyrimidines.

Catabolism of Pyrimidines

Degradation of Uracil and Thymine

The cleavage of uridine and thymidine by phosphorylases (Figure 1, no. 19–20; Figure 4) to the appropriate base and ribose-1-phosphate is the key to the catabolic pathway. Ribose-1-phosphate is transduced via ribose-5-phosphate to the pentose phosphate pathway of cells, whereas deoxyribose-1-phosphate is cleaved by deoxyribose-phosphate aldolase to acetaldehyde and glyceraldehyd-3-phosphate. Although the biochemical strategies used in the *de novo* and salvage pathways of pyrimidines seem to be similar in all organisms, this is not the case for the degradation of the pyrimidine bases. In most eukaryotes and some bacteria, the first step of uracil and thymine degradation is catalyzed by the flavoenzyme dihydropyrimidine dehydrogenase (DPD) (Figure 4, no. 21), which reduces the bases to dihydrouracil and dihydrothymine,

Figure 4 Degradation of pyrimidine bases. Three enzymes (given in numbers) perform the degradation of the pyrimidine ring. Dihydropyrimidine dehydrogenase (21), dihydropyrimidinase (22), and ureidopropionase (23). The formation of malonyl-CoA from β-alanine and methylmalonyl-CoA from β-aminoisobutyrate as well as their final degradation is by usual metabolism and not specified here.

respectively. Hydrolytical cleavage of the pyrimidine ring is performed by dihydropyrimidine amidohydrolase (dihydropyrimidinase, no. 22). Ureidopropionase (no. 23) eliminates CO₂ and NH₃ and produces β-alanin and β-aminoisobutyric acid. These metabolites are excreted in urine of humans or converted to malonyl-CoA and methylmalonyl-CoA, respectively, by different enzymes, as is different the further catabolism through the usual ways for odd-chain fatty acids or branched amino acids. Thus, pyrimidine degradation does not produce problems for the human body – rather it contributes to ATP production – in contrast to urate, which is produced from the purines and can precipitate, causing gout in humans. In some unicellular organisms, other catabolic pathways of uracil have been described, for example, an oxidative one with barbituric acid as intermediate, and malonic acid and urea as the end products.

Regulation

In mammals, dihydropyrimidine dehydrogenase activity (Figure 4, no. 21) catalyzes the rate-limiting step in the degradation pathway. It has been found in the cytosol of cells in many tissues of the body, whereas high activity of dihydropyrimidinase was associated with liver and kidney (Figure 4, no. 22) and that of ureidopropionase with liver only (Figure 4, no. 23). This tissue can guarantee the support with NADPH, required for the reduction of the pyrimidine ring, as well as the speedy and complete catabolism to CO₂ and ammonia.

Deficiency and Interference

The examination of urine and plasma samples for elevated levels of uracil and thymine or other intermediates, set first diagnoses of a complete or partial deficiency of pyrimidine degradation enzymes until molecular analyses allowed identification of quite different mutations. Convulsive disorders, motor retardation, epilepsy, or mental retardation was observed in patients with DPD or dihydropyriminase deficiency. The onset of clinical symptoms usually occurred during childhood. The fundamental importance of DPD for the degradation of pharmacological pyrimidine analogs became evident when patients with partial DPD deficiency suffered from severe neurotoxicity following 5-fluorouracil chemotherapy. β-Alanin is thought to function as neurotransmitter in view of its chemical similarity to the well-known γ-amino-butyric acid (GABA). The altered concentration of β-alanine and the exposure of the nervous system to high concentrations of uracil and thymine have been supposed as contributing factors to the

cerebral dysfunction. Therefore, inhibitors developed for the study of catabolic pathway enzymes are presently not of clinical relevance.

Pyruvate Kinase

K Uyeda, University of Texas Southwestern Medical Center & Veteran Affairs Medical Center, Dallas, TX, USA

© 2013 Elsevier Inc. All rights reserved.

Glossary

Carbohydrate Response Element A DNA sequence within the promoter of a gene to which a specific transcription factor binds in response to excess carbohydrate.

Gene Promoter A region of a gene that responds to glucose, hormones, and other stimuli and binds a number of transcription factors that affect transcription.

Liver Pyruvate Kinase An isoenzyme of pyruvate kinase that occurs mainly in liver.

Pyruvate Kinase M2 (fetal isoform) A fetal isoenzyme of pyruvate kinase M₂ may aid in promotion of cancer cell growth.

Transcription Synthesis of messenger RNA (mRNA) transcribed from a specific sequence of DNA of a gene.

PK Reaction

Pyruvate kinase (PK) (EC 2.7.1.40) catalyzes the final step of glycolysis:

The enzyme requires two equivalents of divalent cation and K⁺ for a full activity. One divalent cation complexes with adenosine triphosphate (ATP) or adenosine diphosphate (ADP) and the other cation binds to the protein and functional groups of pyruvate. The γ -phosphate of ATP bridges the two divalent cations.

Structure

All PKs from a variety of sources are tetramers (Mr = 240 kDa). Mammals express four isozymes designated as M1 and M2 for muscle type, L for liver, and R for erythrocytes. M1 muscle isozyme is the only PK exhibiting hyperbolic kinetics for PEP. However, in the presence of the allosteric ligand such as phenylalanine, it shows cooperative saturation for PEP. All other isozymes exhibit cooperativity with respect to PEP and are activated by fructose 1,6-diphosphate (Fru1,6-P₂) by lowering K_{PEP}.

PK has been isolated and characterized from a number of prokaryotes and from eukaryote tissues. Each consists of 500 amino acid residues. Crystal structures of the enzymes from cat and rabbit muscle, yeast, *Escherichia coli*, and *Leishmania mexicana* have been reported (1 and 2 (review)). They all exhibit a very similar three-dimensional (3-D) structure (Figure 1 (a)). Each subunit contains three domains: the A domain with the classic (α/β)₈ structure; the B domain with an irregular fold; and the C domain with an α - and β -organization (Figure 1 (b)). The eukaryotic enzymes contain additional short N-terminal peptides. The active site is situated on the C-terminal side of the A domain, facing the cleft between the A and B domains. The Fru 1,6-P₂ complex of yeast PK has revealed that the Fru 1,6-P₂-binding site is located in the C (regulatory) domain, which is 40 Å away from the catalytic center.

Regulation of Liver PK *in vitro*

Effect of pH

In alkaline pH, liver PK (LPK) exhibits a sigmoidal saturation curve with PEP, but at lower pH the enzyme shows Michaelis–

Menten kinetics. The transition between these two enzyme conformational states occurs at a narrow pH range of 6.8–7.3.

Allosteric Effectors

Fru 1,6-P₂ reduces the cooperative effects of PEP and converts the enzyme to a form exhibiting Michaelis–Menten kinetics with a higher affinity for the substrate. ATP and alanine are inhibitors of LPK, and these ligands raise the apparent K_{PEP} to higher values. The inhibitory effect of ATP and alanine is counteracted by PEP and Fru 1,6-P₂. Pig LPK is inhibited by phenylalanine more strongly than alanine.

Phosphorylation/Dephosphorylation

LPK was first shown to be regulated by phosphorylation catalyzed by cyclic adenosine monophosphate (cAMP)-dependent protein kinase (PKA), resulting in loss of the enzyme activity. The phosphate incorporation is 1 mol phosphate per mole enzyme subunit on the N-terminal Ser within the consensus PKA target sequence (ArgArgAlaSerPVal). When the phosphorylated LPK was dephosphorylated by histone phosphatase, the enzyme recovered full activity.

The major effect of phosphorylation is to raise the apparent K_{PEP} approximately threefold (from 0.3 to 0.8 mM). It also increases the Hill coefficient from 1.1 to 1.5. V_{max} remains the same for both enzyme forms. This inhibitory effect of phosphorylation is counteracted by Fru 1,6-P₂ and H⁺. Phosphorylation does not inhibit the rat LPK in the presence of 5 μM Fru 1,6-P₂ at pH 7.3, and the enzyme follows Michaelis–Menten kinetics with K_{PEP} of 0.04 mM. Phosphorylated LPK is more sensitive to inhibition by ATP and alanine than is the dephospho form.

Crystallographic Studies

Crystallographic and mutagenesis studies provided the mechanistic features for the allosteric transition in PK at the molecular level. The enzyme displays significant conformational changes involving all three domains of each subunit in the tetrameric enzyme in moving from the T- to R-state (Figure 2). This model is based on the X-ray structure determination of the allosteric *E. coli* PK in the inactive T-state and the M1 isozyme, which is an active R-conformation. In general, the allosteric

transition involves two types of movements: (1) the rotation of the B and C domains (17° and 15°) within each subunit and (2) a 16° rotation of each subunit within the tetramer. Thus, the allosteric activation of PK appears to involve the rotation of both domain and subunit. This model is further supported by the observation that the 3-D structure of each

domain is not altered by their movement, suggesting that they rotate as rigid bodies connected by flexible hinges. The transition from R- to T-state also causes significant changes in the active site including distortion of the PEP-binding site, suggesting the poor substrate affinity of the T-state. It also shrinks the cleft between the A and C domains preventing effector binding.

The allosteric regulation of pyruvate kinase. *Journal of Biological Chemistry* 275: 18145–18152, with permission.

Figure 2 Schematic representation of the domain and subunit rotations in the T- (left) and R- (right) state transition of PK. Reproduced from Mattevi A, Bolognesi M, and Valentini G (1996). The allosteric regulation of pyruvate kinase. *FEBS Letters* 389: 15–19, with permission.

These kinetic changes induced by various ligands and by phosphorylation are the acute regulation of PK activity by hormonal and nutritional states. Experiments performed on intact animals confirm the regulation of PK *in vivo*. Intravenous administration of glucagon causes rapid inactivation of PK in liver. The effect of glucagon also raises cAMP concentration. Insulin causes rapid activation of PK.

Regulation of LPK Concentration by Gene Expression

Effect of Insulin, Glucagon, and Carbohydrate in Liver

In long-term regulation, LPK gene expression is controlled also by hormones and nutrients. Feeding mammals a diet rich in carbohydrate and low in fat leads to an immediate increase in the insulin levels and a fall in glucagon. Insulin and glucagon can activate and repress, respectively, the LPK transcription. These hormonal effects are mediated by direct response to the hormonal signals acting via membrane receptors.

In addition to increased insulin secretion, the excess glucose leads to activation of LPK gene transcription. This activation of gene expression is mediated by glucose, independent of insulin, and requires metabolism of glucose. Thus, glucose is not only a source of energy but also is able to stimulate glycolytic, and lipogenic enzyme genes independent of insulin.

Carbohydrate Response Element of LPK Promoter

The LPK gene promoter contains the glucose response element (−168 to −145 nucleotides upstream of open reading frame) and several other nuclear factor (NF)-binding sites including NF and HNF4. The transcription factor binding to the glucose response element was identified recently and termed carbohydrate response element-binding protein (ChREBP). In addition, it contains multiple phosphorylation sites, subject to regulation by protein kinases/phosphatase.

These kinetic changes induced by various ligands and by phosphorylation are the acute regulation of PK activity by hormonal and nutritional states. Experiments performed on intact animals confirm the regulation of PK *in vivo*. Intravenous administration of glucagon causes rapid inactivation of PK in liver. The effect of glucagon also raises cAMP concentration. Insulin causes rapid activation of PK.

PK M2 (Fetal Isoform) Mediates the Warburg Effect

For over a century now, it has been appreciated that O₂-deprived cells exhibit increased conversion of glucose to

lactate. Otto Warburg observed 70 years ago that cancer cells metabolize glucose more rapidly than normal cells under aerobic conditions. This has become known as the Warburg effect or an enhanced rate of aerobic glycolysis. The mechanisms for these effects are not understood. A recent report has demonstrated that a fetal isoform of PK, PKM2, binds phosphotyrosine (p-Tyr) peptides and may aid in promoting cancer cell growth. No other PK isoforms possess this property, and cancer cell lines exclusively express the PKM2 isoform. Investigators have found that the p-Tyr binding promotes the release of a tightly bound allosteric activator, fructose 1,6-bisphosphate, resulting in the inhibition of enzyme activity for PKM2. It has also been demonstrated that this inhibition of PKM2, by the p-Tyr binding, diverts some of the glucose metabolites from energy production via glycolysis/oxidative phosphorylation to anabolic processes, especially when cells are stimulated by growth factors. These specific metabolites have not been identified, but the results suggest that expression of p-Tyr PKM2 may be important for rapid growth of cancer cells.

Glossary

Antioxidants Molecules capable of preventing the propagation of free radicals and, hence, protecting cellular and extracellular biomolecules from free-radical-induced damage, such as lipid peroxidation and genetic mutations in DNA. There are water-soluble antioxidants, such as ascorbic acid (vitamin C), and lipid-soluble antioxidants, such as α -tocopherol (vitamin E). Ubiquinol belongs to this latter category.

Chloroplasts Organelles present in photosynthetic higher plants and in eukaryotic algae that carry out the process of oxygen-evolving photosynthesis by extracting electrons from water, in a complex electron transfer chain containing plastoquinone among other components, and reducing CO_2 , thus, yielding carbohydrates by a complex synthetic process (Calvin cycle).

Coenzyme A nonprotein compound required for the catalytic action of an enzyme that can be strongly bound to the enzyme itself as a prosthetic group or participate as a substrate to the enzyme-catalyzed reaction. Several coenzymes cannot be synthesized *de novo* and derive from nutritionally supplied vitamins.

Free radical An atom or molecule having one or more unpaired electrons. For this reason, free radicals are usually very reactive, in the attempt to donate or receive an electron, and may damage biological molecules by establishing a chain reaction of propagation followed by permanent chemical

modification of the attacked molecules. Among free radicals are some of the so-called reactive oxygen species, derived by partial reduction of molecular oxygen during mitochondrial respiration and other biological processes.

Mitochondria Organelles present in most eukaryotic cells carrying out the process of oxidative phosphorylation and several other metabolic pathways. Mitochondria consist of two membranes, the inner membrane being the site of the respiratory chain, delimiting two aqueous compartments (called the intermembrane space and the matrix).

Supercomplex A stable protein assembly consisting of different respiratory complexes immobilized by strong specific interactions that lead to a nonrandom supramolecular organization of the proteins in the membrane. The function of the supercomplexes appears not to be restricted to kinetic advantages in electron transfer along the respiratory chain, but they have a role in the stability and assembly of the individual complexes and in preventing excess oxygen radical formation. There is increasing evidence that disruption of the supercomplex organization leads to functional derangements responsible for pathological changes.

Vitamin A biological molecule, acting in small amounts (therefore, not a structural component), which cannot be synthesized by the body and, therefore, requires dietary supplementation. Many vitamins are part of coenzymes. Vitamins are classified as water soluble and lipid soluble.

Chemistry of Quinones

Quinones are diketones derived by oxidation of dihydroxyar- enes; the simplest quinones are those derived by benzenediols (1,2- and 1,4-dihydroxybenzene):

Also condensed arenes give quinones, for example, the naphthoquinones:

1,2-Naphthoquinone

1,4-Naphthoquinone

The reversible oxidation of dihydroxyarenes to the respective quinones is a two-electron process with the intermediate formation of the radical form of semiquinones, for example,

p-Benzosemiquinone

The redox systems quinone/diphenol (or quinol) are widely present in nature. Also known is the charge-transfer complex quinhydrone, where quinone is the electron acceptor while diphenol is the electron donor:

Quinhydrone

Biological Benzoquinones: Coenzyme Q and Plastoquinone

Chemistry and Distribution

Coenzyme Q was discovered in 1957 by FL Crane in Wisconsin as a yellow oily substance, extracted from bovine heart mitochondria, and having redox properties. It is also called ubiquinone, initially from the European nomenclature. The bovine compound is 2,3-dimethoxy-5-methyl-6-decaprenyl-1,4-benzoquinone (coenzyme Q₁₀), but other homologs exist having polyprenyl chains of different lengths in the 6-position (Table 1). Also, some analogs with different substitutions in the benzene ring have been found in nature or synthesized.

Coenzyme Q homologs were initially found in the inner membrane of mitochondria of eukaryotic cells and in the plasma membranes of aerobic and photosynthetic bacteria and they were discovered to be essential components of respiratory and photosynthetic chains. A different analog, plastoquinone-9 (2,3-dimethyl-5-nonaprenyl-1,4-benzoquinone), was found in chloroplasts of higher plants and algae and in cyanobacteria and proved as an essential component of the photosynthetic apparatus (see structure below).

Table 1 Naturally occurring homologs and analogs of coenzyme Q

Homolog or analog	Molecular weight	Occurrence
Coenzyme Q ₆	590	<i>Saccharomyces cerevisiae</i> and other yeasts
Coenzyme Q ₇	659	Minor component of some yeasts
Coenzyme Q ₈	728	Some yeasts, <i>Escherichia coli</i> , and many other bacteria
Coenzyme Q ₉	794	Rat, mouse, shark, some insects, protozoa, molds, yeasts, basidiomycetes, <i>Pseudomonas fluorescens</i> , and other bacteria
Coenzyme Q ₁₀	862	Most mammals including man, birds, amphibia, most invertebrates, most photosynthetic bacteria, and some other bacteria
Rhodokinone-10	847	<i>Rhodospirillum rubrum</i>
Ubichromenol-10	862	Accompanies Q ₁₀ in minor amounts as a cyclization product
Plastoquinone-9	747	Chloroplasts of higher plants and algae

See text for chemical structures. Rhodokinone-10 is 2-methoxy-3-amino-5-methyl-6-decaprenyl-1,4-benzoquinone.

Plastoquinone-9

Soon after its discovery, coenzyme Q was also found to be present in other cellular membranes of eukaryotic cells, including Golgi apparatus, lysosomes, and plasma membrane.

The major redox forms of coenzyme Q, with their prevalent protonation states, are the following:

Ubiquinone (Q)

 Ubisemiquinone anion (Q^{•-})

 Ubiquinol (QH₂)

The standard redox potential of the ubiquinone/ubiquinol couple at pH 7 is ~+100 mV. The semiquinone radical is

intermediate in most redox reactions of coenzyme Q; however, it is very unstable and is rapidly dismutated to the quinone and quinol forms:

Under some conditions, ubiquinones undergo cyclization between the ring and the first isoprenoid unit of the side chain forming the respective ubiquinomenols:

Coenzyme Q homologs 1–12 are soluble in most organic solvents but not in water due to their isoprenoid sidechains. Only homologs 6–12 are obtained in crystalline form at room temperature. In water, coenzyme Q homologs form micelles or aggregates. They are soluble in lipids and disperse in monomeric form in phospholipid bilayers as well as in biological membranes.

Coenzyme Q absorbs light in the UV with a maximum at 275 nm in ethanol and at 270 nm in hydrocarbons when in oxidized form (extinction coefficient $15 \text{ mM}^{-1} \text{ cm}^{-1}$), and with a maximum at 290 nm in all organic solvents when in reduced form (extinction coefficient $4 \text{ mM}^{-1} \text{ cm}^{-1}$). The ubisemiquinone anion has a maximum at 318 nm (extinction coefficient $10.7 \text{ mM}^{-1} \text{ cm}^{-1}$) and minor peaks also in the visible spectrum. The semiquinones are best detected by electron spin resonance techniques.

The lateral mobility of coenzyme Q in phospholipid bilayers is very high: using the method of collisional fluorescence quenching with membrane-bound fluorescent molecules, a lateral diffusion coefficient was calculated $\sim 10^{-7} \text{ cm}^2 \text{ s}^{-1}$.

Such mobility seems essential for the function of the quinone in electron transfer chains in energy-transducing membranes.

Functions of Coenzyme Q

Electron transfer chains of mitochondria and bacteria

The best-known function of coenzyme Q is as a redox component of the mitochondrial respiratory chain, localized in the inner membrane. The structural organization of the mitochondrial oxidative phosphorylation (OXPHOS) system has received large attention in the past and most investigations led to the conclusion, accepted till recently, that the respiratory enzymatic complexes are randomly dispersed in the lipid bilayer of the inner membrane and functionally connected by fast diffusion of smaller redox components, coenzyme Q and cytochrome *c*. As shown in the standard scheme of the respiratory chain depicted in Figure 1.

Coenzyme Q was first described as a mobile diffusible component localized between complex I (reduced nicotinamide adenine dinucleotide (NADH) coenzyme Q reductase) or complex II (succinate coenzyme Q reductase) and complex III (ubiquinol cytochrome *c* reductase); in these systems, coenzyme Q is reduced by complex I or II and reoxidized by complex III. It was then found that coenzyme Q is also reduced by other mitochondrial enzymes, such as glycerol-1-phosphate dehydrogenase, electron transfer flavoprotein dehydrogenase (an enzyme involved in fatty acyl CoA oxidation), and dihydro-orotate dehydrogenase.

Due to its extremely hydrophobic nature, coenzyme Q is localized in the hydrocarbon interior of the lipid bilayer of the inner mitochondrial membrane, where its diffusion rate may be very high. In this way it behaves as a common pool of molecules, so that any molecule would be randomly reduced by any complex I or II and reoxidized by any complex III. Major observations in support of this model were the random distribution of the intramembrane particles observed

Figure 1 Schematic view of the mitochondrial oxidative phosphorylation system, showing the role of coenzyme Q as a shuttle of electrons between complex I or complex II and complex III. Other dehydrogenases using coenzyme Q as acceptor are not shown for simplicity. Roman numbers refer to the respective enzyme complexes. Black arrows indicate the flux of electrons, green arrows indicate chemical reactions, and blue arrows indicate proton translocation. During redox reactions catalyzed by complex I, III, and IV, protons are extruded forming a transmembrane gradient that is used by complex V (adenosine triphosphate (ATP) synthase) for synthesizing ATP.

Figure 2 The Q-cycle as a mechanism of proton translocation in complex III of the mitochondrial respiratory chain. The scheme shows the Q-cycle in the context of the enzyme structure where the catalytic subunits are shown by their surfaces and made transparent so as to show the redox centers (cyan: cytochrome *b*; yellow: iron-sulfur protein; blue: cytochrome *c*₁). Quinol (QH₂) is oxidized in a bifurcated reaction at the Q₀-site of the complex located at the outer positive side of the membrane (P-phase): one electron is transferred to the high-potential chain, consisting of the Fe₂S₂ center and cytochrome *c*₁, and then to cytochrome *c* (red) that carries the electron to complex IV. As the semiquinone formed (SQ₀) is unstable, another electron is transferred through the low-potential chain of cytochrome hemes (*b*_L and *b*_H) to the Q₁-site where a quinone molecule is fully reduced to quinol. To provide the two electrons required at the Q₁-site, located at the inner negative side of the membrane (N-phase), the Q₀-site oxidizes two equivalents of quinol (2 × QH₂) in successive turnovers. Information about inhibitor specificity of the above-mentioned reactions is shown in the figure. The integration of the redox reactions with the release or uptake of protons in the aqueous phases (red arrows) allows the complex to pump protons across the membrane. Figure courtesy: Dr. A. R. Crofts, University of Illinois at Urbana-Champaign, IL, USA.

by freeze-fracture electron microscopy and the kinetic demonstration that coenzyme Q (as well as cytochrome *c*) behaves as a homogeneous pool. However, more recent investigations by native gel electrophoresis have shown the existence of supra-molecular associations of the respiratory complexes (super-complexes), confirmed by electron microscopy analysis and single-particle image processing. Flux control analysis has demonstrated that complexes I and III in mammalian mitochondria and complexes I, III, and IV in plant mitochondria kinetically behave as single units, suggesting the existence of substrate channeling within the supercomplexes.

Besides coenzyme Q dissolved in the lipid bilayer or in lipid domains within supercomplexes, coenzyme Q molecules bound to the individual complexes have also been described. These bound quinones may be important for the mechanism of outward proton translocation, required in the chemiosmotic mechanism of OXPHOS. The best-known mechanism is the Q-cycle, first proposed by the Nobel laureate Peter Mitchell (Figure 2).

Tight coenzyme Q binding to proteins (Q-binding proteins) in the respiratory complexes is required to stabilize the

Figure 3 Bound quinones in the photosynthetic reaction center of *Rhodospseudomonas viridis*. Following excitation, the special pair of bacteriochlorophyll molecules donates an electron to a nearby bacteriopheophytin pigment (time constant: 3 ps). Subsequent transfer to the primary quinone (QA, a bound menaquinone) occurs with a half-time of 200 ps. Further electron transfer occurs from QA to the quinone acceptor QB, a bound ubiquinone occupying an active site near the cytoplasmic surface of the protein. QB accepts two electrons and two protons, then it undergoes exchange with the mobile pool of quinones in the lipid bilayer. With permission of Dr. R. Baxter, University of Chicago, IL, USA.

semiquinone form that is an essential intermediate in the mechanism of proton translocation.

Moreover, a well-known example of bound quinones is represented by the reaction center of photosynthetic bacteria that has been crystallized and resolved by X-ray diffraction together with its bound prosthetic groups (Figure 3). In bacteria, besides ubiquinone, menaquinone (a naphthoquinone) also may participate in electron transfer.

In chloroplasts of photosynthetic algae and higher plants, the function of ubiquinone is exploited by plastoquinone, present in bound form in photosystem II and free as a pool in the lipid bilayer.

Other electron transfer chains

Coenzyme Q of eukaryotic cells is present in most intracellular membranes and in the plasma membrane as well. Its function in these systems is better known in the plasma membrane oxidoreductase where the quinone appears to participate in transmembrane electron transfer between intracellular NADH or NADPH and extracellular acceptors including the ascorbic acid free radical, derived from the partial oxidation of ascorbic acid. This system may be involved in the antioxidant defenses of the cell because it regenerates ascorbic acid, an antioxidant.

Coenzyme Q as an antioxidant

Coenzyme Q and other quinones are powerful antioxidants in their reduced form. The ubiquinol reacts with peroxide radicals, such as the lipid peroxide radical LOO·:

Figure 4 Simplified scheme of the biosynthesis of coenzyme Q. R, isoprenoid side chain; HMG-CoA, 3-hydroxy-3-methyl-glutaryl coenzyme A.

where LOOH is a lipid hydroperoxide.

In addition, it may be used to regenerate the reduced antioxidant form of vitamin E (α -tocopherol, T-OH) from the tocopheroxyl radical TO $\cdot$:

The semiquinone form of coenzyme Q, originated from its antioxidant action, is readily converted to the oxidized form by another radical:

The cell contains several enzymatic systems to reduce oxidized coenzyme Q (Q) back to its antioxidant form (QH $_2$). Among these are the cytosolic enzyme DT-diaphorase (NAD(P)H dehydrogenase (quinone) E.C.1.6.99.2; DT = formerly DPNH/TPNH, now NADH/NADPH), also found bound to the plasma membrane, a cytosolic NADPH quinone reductase, and microsomal NADH cytochrome b_5 reductase.

Biosynthesis of coenzyme Q

Coenzyme Q is synthesized by animals starting from the amino acid tyrosine which is converted to *p*-hydroxybenzoate; after insertion of the isoprenoid side chain in the 6-position, the ring is completed by a complex series of reactions involving hydroxylations and O-methylations. The isoprenoid side chain is synthesized starting from acetyl CoA through the mevalonate pathway and isopentenyl pyrophosphate, which is common to the synthesis of cholesterol, dolichol, and other polyprenyl compounds (Figure 4). It was found that cholesterol-lowering agents acting on the enzyme 3-hydroxy-3-methyl-glutaryl CoA reductase, which converts 3-hydroxy-3-methyl-glutaryl CoA to mevalonate, besides lowering plasma cholesterol, also lower coenzyme Q levels, suggesting caution in the use of these agents.

A complex of at least 10 proteins encoded by nuclear (COQ) genes synthesizes CoQ but its regulation is not clear. Since 1989, a growing number of patients with multisystemic mitochondrial disorders and neuromuscular disorders showing deficiencies of CoQ have been identified. CoQ deficiency caused by mutation(s) in any of the COQ genes is designated primary deficiency. Other patients have displayed other genetic defects

independent on the CoQ biosynthesis pathway, and are considered to have secondary deficiencies.

The biosynthesis of coenzyme Q also requires several vitamin-derived coenzymes and appears to be easily limiting on the normal levels of the quinone in the body. For this reason, dietary intake of coenzyme Q, as a vitamin-like supplement, has been recommended by many authors.

Biological *o*-Benzoquinones Derived from Catecholamines

Some *o*-quinones may be physiologically formed from catecholamine derivatives. Adrenaline may undergo oxidation and cyclization to adrenochrome in a multistep process, in which the main oxidant under physiological conditions is the superoxide anion (Figure 5); on the other hand, adrenochrome can be reduced to the corresponding semiquinone by NADPH-cytochrome P450 reductase in liver microsomes and by mitochondrial complex I in bovine heart; a redox cycle is then established in which the semiquinone reacts with O $_2$, producing superoxide and regenerating adrenochrome. Similar reactions occur with dopamine and dopaminochrome. Substantial evidence exists that aminochromes and their chemical derivatives initiate deleterious effects at the cellular level that affect the supply of energy for the maintenance of vital cellular processes, particularly in the heart.

Biological Naphthoquinones: Menaquinone and Vitamin K

Menaquinone is the quinone used for electron transfer by many bacteria, either alone or together with ubiquinone (Figure 3).

Figure 5 Redox cycling of catecholamines: the example of adrenaline is shown in the figure. Adrenaline is first oxidized to adrenochrome that is reduced by complex I by one electron transfer to the semiquinone that, on the other hand, auto-oxidizes generating superoxide and perpetuating the cycle.

Figure 6 Mechanism of action of vitamin K in protein carboxylation. The γ -carboxylation reaction of protein-bound glutamate requires molecular oxygen and the reduced form of vitamin K (1); the hydroquinone is converted to the vitamin K epoxide (2) during the reaction. The vitamin K epoxide must be reconverted to the hydroquinone; this happens in two steps: in the first step, the epoxide is converted to the quinone form (3) using the coenzyme thioredoxin $[R(SH)_2]$; the quinone is then reduced to the hydroquinone in an NADPH-dependent reaction.

Vitamin K exists in two natural forms, phyloquinone (K1) and menaquinone (K2), with 4 and 6 isoprenoid units, respectively. In phyloquinone, three isoprenoid units are hydrogenated. Menadione (K3), without an isoprenoid chain, is a synthetic derivative.

Vitamin K is involved in the process of blood coagulation, being required for the synthesis of prothrombin and factors VII, IX, and X. Vitamin K is involved in posttranslational modifications of these proteins consisting in the γ -carboxylation of glutamate residues. Vitamin K is the coenzyme of the carboxylase enzyme and acts in its reduced hydroquinone form. The mechanism of action is shown in [Figure 6](#).

Rab Family

M W McCaffrey and A J Lindsay, University College Cork, Cork, Republic of Ireland

Published by Elsevier Inc.

Glossary

Effectors Proteins which are necessary to effect small guanine triphosphatase (GTPase) function. Many (putative) effectors of the ras superfamily have been described in the past decade.

Guanine nucleotide diphosphate (GDP) As for GTP but lacking the terminal (high energy phosphate bond/group).

Guanine nucleotide triphosphate (GTP) A compound – termed a purine – that comprises of two (carbon and nitrogen containing) cyclic rings, a five carbon sugar, and three phosphate groups.

GTPases Proteins capable of binding and hydrolyzing GTP by cleavage of its terminal phosphate. This reaction results in the protein being switched to the inactive state, that is, associated with GDP.

Ras Monomeric GTPases, first identified as oncogenes/oncoproteins, which function as central players in mitogenic signaling pathways.

Rho The first ras homolog to be identified, rho proteins control actin cytoskeleton organization and structure.

Discovery

The first Rab guanine triphosphatases (GTPases) were discovered in the late 1980s, through the pioneering work of the Tavittian group, in Paris, which set out to identify homologs of the ras oncogenes. They screened a brain complementary DNA (cDNA) library with degenerate oligonucleotides designed against the most conserved regions of G proteins (the G boxes), as well as known G proteins, new ras-related genes were identified in this screen. These were sufficiently different from ras and rho to be placed in a new family of the ras superfamily and were named the Rabs–Ras homolog from brain.

Sequencing revealed that these new Rab genes bore greatest similarity to two previously described yeast secretory mutant genes, *sec4* and *ypt1*. The fact that these two yeast orthologs had previously been implicated in membrane trafficking provided the first clues that the members of the Rab GTPase family function in membrane trafficking in higher eukaryotes. In the years that followed, several research groups (notably the Zerial group) extended the family to 11 then to between 30 and 40 distinct members. With the aid of information from the human genome project, up to 70 distinct mammalian Rab GTPases have now been identified.

Primary Structure and Evolution

The Rab family are the most divergent and extensive branch of the ras superfamily. They contain approximately 200 amino acids with a molecular mass between 20 and 25 kDa, and are

hydrophilic in nature (see [Figure 1](#) for a schematic representation of Rab functional domains). Like all G proteins, they contain well-conserved guanine nucleotide-binding domains (G boxes) but otherwise are quite divergent – particularly in their carboxy-terminal region. This region is known to be critical for specifying membrane localization.

Their extreme carboxy-termini also possess a characteristic conserved CC or CXC motif (C=cysteine and X=any amino acid). This motif is posttranslationally modified, in a process known as ‘isoprenylation’, by the addition of geranyl groups. The addition of a hydrophobic moiety on the cysteine results in a protein that is chemically competent for insertion into the lipid bilayer (see later for further details on posttranslational modifications).

By analogy with the Ras proteins, a further domain has been identified in the Rabs – the effector domain. This domain of approximately 10 amino acids was found to be critical for transmission of the Ras signal to its downstream machinery. Mutation of this effector domain abolishes growth signaling, independent of Ras GTP binding. Thus, this region was named the effector domain of ras. The equivalent region in the Rabs, also termed the ‘effector’ domain, is frequently mutated in studies that investigate Rab function.

By analogy with the oncogenic Ras mutants, a number of Rab mutations have been generated. The most frequently utilized activating mutant for the Rabs is at amino acid position approximately 70 and is generated by the conversion of a glutamine (Q) to a leucine (L) at this position. Such Rab mutants are deficient in GTPase activity and thus remain in the activated GTP-associated state (see [Figure 2](#) for GTP structure). A serine

Figure 1 Schematic diagram of the general domain structure of Rab GTPases. Indicated are the commonly used Rab11 mutations and their biochemical consequences.

Figure 2 The structure of GTP.

(S) to asparagine (N) mutation, near amino acid 20, generates a dominant negative Rab mutant that is constitutively GDP bound and therefore inactive. Expression of these mutants in mammalian cells has revealed important Rab functional data.

In a study of the evolution and complexity of the core protein machinery involved in intracellular trafficking (coat complexes, Rab GTPases, SNAREs, and Sec1s) by the Scheller group, 60 distinct Rab genes were identified in humans. It was noted that there was a significant expansion of the Rab family from yeast to worms, and a further expansion from worms to mammals. A phylogenetic tree of the human Rab family is shown in [Figure 3](#). Of the four core membrane trafficking families compared, the Rabs were the only family that underwent such a significant expansion. It is likely that the higher degree of complexity in multicellular organisms is reflected by the greater requirement for Rabs, not only for more intricate regulation of intracellular trafficking but also for tissue specialization of membrane trafficking functions.

The Rab family can be divided into ~10 subfamilies. Representative members of these subfamilies are Rab1, Rab3, Rab4, Rab5, Rab6, Rab8, Rab11, Rab22, Rab27, and Rab40.

Posttranslational Modifications

Rab proteins are hydrophilic; thus, in order for membrane binding they must possess one, or two, C20 geranyl-geranyl lipid groups at their carboxy-terminus. The process by which they gain these lipid moieties is known as 'isoprenylation'. Newly synthesized, unprenylated, Rab GTPases are bound by Rab escort protein (REP) and delivered to geranylgeranyl transferase (GGTase). GGTase catalyzes the attachment of the lipid groups to two carboxy-terminal cysteine residues present on all

Rab GTPases. REP appears to be a specialized Rab GDI that can deliver newly synthesized, GDP-bound, Rab proteins to GGTase for isoprenylation, and then transport the modified protein to its target membrane. It is thought that Rab-GDP binds its host membrane via a protein receptor, which senses the Rab carboxy-terminal domain; however, very little evidence currently exists in the literature regarding the identity of such Rab receptors. Thus, while the amino acid sequence in the C-terminal region confers membrane specificity to a given Rab, the isoprenoid group confers chemical compatibility with the membrane, anchoring the otherwise hydrophilic protein in the hydrophobic lipid bilayer.

Cellular Localization

Rab proteins have now become standard markers for organelles of the secretory and endocytic pathways. Not all Rab GTPases have yet been sufficiently characterized such that the entire Rab localization pattern is known. However, for those that have been characterized, it is clear that they localize to distinct membrane organelles. For example, Rab1 localizes to the endoplasmic reticulum (ER)/cis-Golgi and Rab3 localizes to synaptic vesicles/chromaffin granules of the neuroendocrine system, while Rab5, Rab4, and Rab11 localize to distinct early endosomal membranes, Rab6 is located on the Golgi apparatus, Rab7 is on late endosomes, Rab22 localizes to endosomes and the Golgi, and Rab27 to melanosomes and lytic granules. [Figure 4](#) and [Table 1](#) indicate the known localization and trafficking steps controlled by Rabs characterized to date.

Functional Cycle

The functional cycle of Rab5 has been extensively characterized and is used here as a paradigm of all Rabs (see [Figure 5](#) for generalized Rab GTPase cycle). GDP-bound Rab5 is delivered to its target membrane by Rab guanine nucleotide dissociation inhibitor (Rab GDI). Rab guanine nucleotide exchange factor (Rab GEF) then catalyzes the exchange of the GDP for GTP, allowing Rab5 to adopt its active conformation. The GTP-bound Rab is now resistant to extraction by Rab GDI. Once membrane associated and in its active conformation, the Rab

Figure 3 Phylogenetic tree of the human Rab GTPases. From Bock JB, Matern HT, Peden AA, and Scheller RH (2001) A genomic perspective on membrane compartment organization. *Nature* 409: 839–841.

protein is now competent to exert a controlling function on membrane trafficking. Rab5 mediates its function by recruiting a repertoire of specific effector proteins necessary for fusion of early endosomes. Upon completion of Rab function, the GTP

is hydrolyzed by the Rab GTPase enzymatic activity, releasing inorganic phosphate and resulting in an inactive Rab bound to GDP. This GTPase activity is stimulated by Rab GTPase activating protein (Rab GAP).

Figure 4 Localization of selected Rab GTPases and the membrane trafficking pathways they regulate. The endocytic pathway involves internalization of cargo in clathrin-coated vesicles (CCV) and delivery to the early/sorting endosome (SE). Cargo is then either sorted for transport along the degradative pathway to the late endosomes (LE) and lysosomes (Lys), or directly recycled back to the plasma membrane from the SE, or indirectly, via the endocytic recycling compartment (ERC). The biosynthetic pathway transports proteins from the endoplasmic reticulum (ER) through the Golgi complex from where they are delivered to the cell surface in secretory vesicles (SV). The endocytic and secretory pathways communicate through the *trans*-Golgi network (TGN).

Rabs have been variously implicated in vesicle budding from the donor membrane, transport along the cytoskeleton, docking to, and fusion with, the acceptor membrane. Though there is evidence for various Rabs of their involvement in these distinct events in membrane trafficking, it is not clear whether some Rabs function in vesicle budding exclusively, while others function in vesicle transport or docking, or whether a given Rab, in association with one specific set of effector proteins, functions in budding and in combination with other sets of effector proteins functions in transport, docking, or fusion.

Effectors

Several putative Rab effectors have been identified – primarily by two-hybrid library screening with GTPase deficient (dominant-positive) Rab mutants. While a survey of all of the Rab effectors reported in the literature is beyond the scope of this article, it is clear that there are likely to be many more Rab effectors than Rab GTPases. The GTP-bound form of Rab5 has been shown to interact specifically with at least 20 different proteins. Several Rab effectors have coiled-coil and/or phospholipid-binding domains (such as FYVE or C2 domains), while some are enzymes, or cytoskeletal (actin or tubulin) motor proteins. Identification of Rab effectors, and regulatory proteins, is a very important approach toward understanding the function of Rab GTPases and is likely to be an area of continued research for several years to come.

Rabs and Diseases

It is well appreciated that a substantial number of disease-causing genes are involved in membrane trafficking. A growing proportion of these genetic diseases are being attributed to mutations of Rab GTPases, or their interacting proteins.

Table 1 Localization, tissue distribution, and function of the human Rab GTPases

Rab GTPase	Localization	Tissue expression	Function
Rab34	Golgi	Ubiquitous	Secretory pathway
Rab36	Golgi	Unknown	Lysosome positioning
Rab28	Endosomes	Ubiquitous	Degradative pathway
Rab40	Golgi?	Unknown	Unknown

Rab33	Golgi	Brain, lymphocytes, melanocytes	Autophagosome formation (Rab33B)
Rab9	LE	Ubiquitous	LE to TGN transport
Rab7	Late endosomes (LE)	Ubiquitous	Transport from LE to lysosomes
Rab17	Epithelial cells	Apical RC	Transport through apical RC
Rab41	Unknown	Widely expressed	Unknown
Rab20	Apical dense tubules in kidney tubule epithelial cells	Epithelial cells	Connexin 43 transport

RPE, retinal pigment epithelium.

Figure 5 The Rab GTPase cycle. Rab GTPase cycle between GTP- and GDP-bound forms, allowing the Rab to adopt active and inactive conformations. The cycle is mediated by various accessory factors. A guanine-nucleotide exchange factor (GEF) exchanges the GDP for GTP. Conversion from the GTP- to the GDP-bound form is mediated by a GTPase-activating protein (GAP) which stimulates the Rab to hydrolyze bound GTP. The active GTP-bound form mediates its function through specific effector molecules. Newly synthesized cytosolic, GDP-bound Rab, interacts with Rab escort protein (REP) for membrane delivery. Subsequently, after each functional round, the GDP-bound Rab is extracted by the GDP dissociation inhibitor (GDI) from its host membrane and delivered to a new membrane location for another functional round.

The first example of Rab involvement in disease was in Griscelli syndrome – an autosomal recessive disorder that results in pigmentation defects. There are two variants of this disease, one that results in immunological defects, and the other is associated with neurological dysfunction. The former is caused by missense mutations in the Rab27a gene, and the latter is the result of mutations in its putative effector, myosin Va. Both genes are located side by side on chromosome 15. Rab27a functions to regulate the transport of melanosomes to the periphery of melanocytes, it also regulates the secretion of lytic granules in cytotoxic T lymphocytes. Hence, the lack of functional Rab27a results in the loss of pigmentation and in the uncontrolled activation of T lymphocytes. Mutation of myosin Va causes pigmentation defects, but since it is not involved in lytic granule movement does not cause immunological defects.

Choroideremia is an X-linked disease that results in the degeneration of the pigment epithelium of the eye. It is caused by a defect in the REP-1 gene. REP-1 is one of the two isoforms of GGTase that prenylate Rab GTPases. It is essential for the prenylation of Rab27a in the retinal pigment epithelium. REP-2 appears to be sufficient for the efficient geranyl-geranylation of all other Rab GTPases. Thus, the lack of functional REP-1 results in nonfunctional Rab27a and the onset of the disease. The pathology of this disease may be caused by the degeneration of the retinal epithelium due to deficient melanosome transport, and hence lack of protection during light exposure.

Tuberin is a tumor-suppressor gene that interacts with Rabaptin-5 and negatively regulates endocytosis by acting as a Rab5-GAP. Its inactivation causes tuberous sclerosis, a disease that results in malformations and tumors of the central

nervous system. Furthermore, mutations in the GDI1 gene, which encodes GDI- α , have been found in a subgroup of patients with X-linked nonspecific mental retardation. GDI- α is particularly abundant in brain tissue, thus defective membrane recycling of one or more Rab GTPases in brain synapses is likely to be the cause of this condition.

In recent years, the involvement of the Rab11/25 subfamily and their effector proteins in cancer and Rab7 in Charcot-Marie-Tooth neuropathies have been described. Specifically, Rab11a has been shown to be involved in low oxygen (hypoxia) stimulated invasion of breast cancer cells. Independently, Rab11c(Rab25) has been shown to determine the aggressiveness of breast and ovarian cancers and its increased expression correlates with poor prognosis. The major underlying basis for the role of Rab25 in cancer aggressiveness appears to be its ability to drive the recycling of the $\alpha 5\beta 1$ integrin to the plasma membrane resulting in increased random three-dimensional (3D) cell motility. Supportive of an underlying role of Rab11 GTPases in epithelial cancer aggressiveness is the fact that two Rab11 effectors – the Rab coupling protein (RCP) and Rab11-FIP3 are separately implicated in human cancers and additionally that RCP drives the recycling of the $\alpha 5\beta 1$ integrin and the epidermal growth factor receptor (EGF-R) to the plasma membrane leading to increased 3D cell motility and growth factor signaling.

Finally, Rab7 has been implicated in a group of autosomal dominant axonal disorders – namely, Charcot-Marie-Tooth

type 2B disease (CMT-2B). This neuropathy is characterized by severe sensory loss often leading to amputations. Rab7, a GTPase which controls late endosomal trafficking, has been implicated in CMT-2B through the identification of a number of missense mutations which render it in the dominant-positive (GTP-bound) form. The molecular basis for the role of Rab7 in CMT-2B is likely to be increased degradation rates of cargo proteins, such as the neurotrophin receptor as a consequence of increased Rab7 activity.

Glossary

GTPase A protein that can bind and hydrolyze GTP.

Guanosine 5'-diphosphate (GDP) A nucleotide analogous to adenosine diphosphate (ADP) that is composed of guanine linked to ribose and two phosphates.

Guanosine 5'-triphosphate (GTP) An energy-rich nucleotide analogous to adenosine triphosphate (ATP) that is composed of guanine linked to ribose and three phosphates.

Interphase A period or stage between two successive mitotic divisions of a cell nucleus.

Mitosis The sequential differentiation and segregation of replicated chromosomes in a cell nucleus that precedes complete cell division.

Nuclear pore complex (NPC) Large organelles of the nuclear envelope through which passage of proteins and RNAs between the cytoplasm and nuclear interior occurs.

Ras related nuclear protein (Ran) is a 25-kDa member of the Ras superfamily of small guanosine triphosphatases (GTPases). To date, a Ran homolog has been found in every nucleated cell of every eukaryotic organism on Earth, and Ran is essential for the viability of all those cells. During interphase, Ran plays an essential role in driving and regulating the active transport of cargo between the nucleus and cytoplasm. Ran also has critical functions during mitosis when Ran is essential for mitotic spindle assembly and placement as well as re-assembly of the nuclear envelope.

Small Guanosine Triphosphate-Binding Proteins as Molecular Switches

Ran is called a GTPase because it binds and hydrolyzes guanosine triphosphate (GTP). All small GTPases of the Ras superfamily cycle between GTP- and guanosine diphosphate (GDP)-bound states, and undergo a marked conformational change upon conversion from one state to the other. Thus, GTPases in the GTP-bound form can bind proteins that the GDP-bound form cannot, and vice versa. This key property confers on small GTPases the ability to function as molecular switches that cycle between active and inactive states, the GTP-bound form generally being the active form.

Ran represents its own family of small GTP-binding proteins in the Ras superfamily, of which it is the only member. The other families include the Ras, Rab, Arf, Rac, and Rho families that regulate signal transduction, vesicular transport, cytoskeletal organization, and cell proliferation. Ran's role is to act as a switch to regulate nuclear transport during interphase and spindle, and nuclear envelope assembly during mitosis.

Nucleocytoplasmic Transport

A basic necessity of the eukaryotic cell is the ability to transport macromolecules bidirectionally between the nucleus and

cytoplasm. The traffic between these two compartments is both heavy and complex with multiple classes of cargo being actively transported in both directions (**Figure 1**). Nuclear proteins such as transcription factors and histones are, like all proteins, made in the cytoplasm and must cross the nuclear envelope into the nuclear interior to carry out their function. Conversely, ribosomal subunits, transfer RNAs (tRNAs), and messenger RNAs (mRNAs) produced inside the nucleus must cross the nuclear envelope in the opposite direction into the cytoplasm in order to be used for protein translation.

Nucleocytoplasmic traffic is restricted to nuclear pore complexes (NPCs), which are large proteinaceous structures that bridge the double membrane of the nuclear envelope to form aqueous channels linking the cytoplasm and nucleoplasm. The vertebrate NPC is composed of ~30 different proteins, and a HeLa cell contains ~3000 NPCs. At present, all NPCs appear to be functionally identical with the same NPC capable of carrying out both import and export virtually simultaneously. While molecules up to ~50 kDa can diffuse through the NPC, the majority of nuclear proteins (both larger and smaller than 50 kDa) as well as the other classes of transport cargo appear to undergo signal-mediated active transport rather than diffusion.

There are two types of nuclear transport signals, nuclear localization sequences (NLSs) that mediate nuclear import and nuclear export sequences (NESs) that mediate nuclear export. There are multiple types of NLSs and NESs found on different types of cargo, and, in general, each type of signal is recognized by a different nuclear receptor/carrier. Most nuclear carriers are members of the karyopherin- β superfamily and there are over 20 members of this family in human cells. During nuclear import, a soluble carrier binds the NLS-containing cargo in the cytoplasm, then moves the cargo through the NPC and releases it in the nuclear interior. Nuclear export works essentially the same way in reverse, with an NES-containing cargo being recognized by its specific carrier inside the nucleus, movement of the export complex through the NPC, and disassembly of the complex and release of the cargo upon reaching the cytoplasm.

Figure 1 Overview of nucleocytoplasmic transport. Most nuclear transport requires nuclear RanGTP, however mRNA export does not. Carriers of the NTF2 family mediate mRNA export, and this transport pathway is Ran-independent. Active transport of the rest of the cargo listed does require nuclear RanGTP.

The Ran GTPase

The Cellular Gradient of RanGTP

A key player in the majority of the known nuclear transport pathways is the small GTPase Ran and, not incidentally, the main region of homology between all the karyopherin- β nuclear carriers is a RanGTP-binding domain. Inside the cell, Ran is primarily nuclear in spite of the fact it does not appear to contain an NLS in its sequence. This is because Ran is actively imported into the nucleus by a small protein called 'p10/NTF2', which is a member of a second class of nuclear carriers, the NTF2 family.

Importantly, whether Ran is in the cytoplasm or nucleus determines whether it is RanGTP or RanGDP (**Figure 2**). Inside the nucleus, Ran is converted to the GTP-bound form by the RanGEF (guanine nucleotide exchange factor), which stimulates RanGDP to release GDP and bind GTP. By contrast, the RanGAP (GTPase-stimulating protein) is located in the cytoplasm. The RanGAP rapidly converts any RanGTP entering the cytoplasm to RanGDP by stimulating Ran to hydrolyze its bound GTP.

The resulting concentration gradient of low RanGTP in the cytoplasm to high RanGTP in the nucleus is vitally important for controlling the directionality of nuclear transport by regulating the assembly and disassembly of karyopherin- β -containing transport complexes. Also, because the RanGEF is bound to chromatin, the concentration of RanGTP is highest near the chromatin where it is produced (**Figure 2(c)**). This

location becomes important during mitosis, when chromatin-localized RanGTP stimulates mitotic spindle and nuclear envelope assembly in the correct location around chromatin.

Cellular Functions of Ran

Nuclear Transport

The increasing RanGTP concentration from the cytoplasm to the nuclear interior is the primary factor that triggers the disassembly of transport complexes at their correct final destination. Members of the karyopherin- β family preferentially bind RanGTP with a much lower affinity for RanGDP and, upon binding RanGTP, the karyopherin- β carrier undergoes a conformational change that alters its cargo-binding domain. NLS receptors of the karyopherin- β family can only bind their cargo when they do not have bound RanGTP, which is their probable state in the cytoplasm. After movement across the NPC into the nuclear interior where the import complex encounters RanGTP, the carrier binds RanGTP and, as a result, releases its cargo into the nuclear interior (**Figure 3(a)**).

Export carriers of the karyopherin- β family behave just the opposite. These export carriers, in order to simultaneously bind their export cargo, must first bind RanGTP. After movement through the NPC, the cargo:export carrier:RanGTP complex encounters the RanGAP in the cytoplasm. Ran is stimulated to hydrolyze its bound GTP and, after hydrolysis, becomes RanGDP. The export carriers have a low affinity for

Figure 2 Establishment of the RanGTP gradient between the cytoplasm and nucleoplasm. (a) The RanGAP, which stimulates Ran to hydrolyze its bound GTP, is restricted to the cytoplasm. (b) The RanGEF, which stimulates Ran to release bound GDP and take up GTP, is found inside the nucleus bound to chromatin. (c) Restricting the RanGAP and the RanGEF to different compartments results in high levels of RanGTP inside the nucleus and low levels of RanGTP in the cytoplasm during interphase (top). The resulting gradient of RanGTP concentration between the cytoplasm and nucleoplasm is the key regulatory mechanism controlling the assembly and disassembly of nuclear import and export complexes in the correct cellular location (see Figure 3). Also, the RanGEF remains bound to chromatin throughout the cell cycle, and production of RanGTP at the chromatin surface in mitotic cells is required for proper placement of the mitotic spindle and re-assembly of the nuclear envelope around chromatin at the end of mitosis (bottom).

RanGDP and, as a result, both RanGDP and an export cargo dissociate from the export carrier in the cytoplasm.

Regulation of Spindle and Nuclear Envelope Assembly at Mitosis

The nuclear envelope vesiculates and breaks apart during mitosis in vertebrate cells, and then reforms after the daughter cells are divided. Accordingly, no nuclear transport occurs during this time because there is no nuclear envelope and the cytoplasmic

and nuclear contents are mixed. Ran, however, has additional functions critical to this period. Nuclear proteins containing an NLS are once again exposed to the NLS receptors and can be rebound by them. However, as during nuclear import, RanGTP can break this complex apart, releasing the proteins.

Many of the proteins responsible for assembly of the mitotic spindle at mitosis are nuclear during interphase and contain an NLS. To be active for spindle assembly, RanGTP must first release these spindle assembly factors from NLS receptors. Because the concentration of RanGTP is highest, close to the chromatin due to the RanGEF located there; active spindle

Figure 3 The RanGTP gradient across the NPC controls the assembly and disassembly of nuclear transport complexes. (a) Nuclear import carriers cannot bind import cargo and RanGTP simultaneously. After import of the import carrier: cargo complex through the nuclear pore complex (NPC), the carrier binds nuclear RanGTP. As a result of binding RanGTP, the import carrier releases the import cargo in the nuclear interior. (b) In contrast to nuclear import carriers, nuclear export carriers require bound RanGTP in order to bind their export cargo with high affinity. After export through the NPC, the export complex (RanGTP: export carrier: cargo) encounters the RanGAP in the cytoplasm that stimulates Ran to hydrolyze its bound GTP. Conversion of RanGTP to RanGDP results in the release of RanGDP and export cargo from the export carrier into the cytoplasm.

assembly factors (as opposed to inactive factors complexed with NLS receptors) are also most concentrated there. RanGTP is thus essential for spindle formation; both to release spindle assembly factors from NLS-binding carriers and for correct orientation of the spindle around chromatin.

As stated above, when a human cell enters mitosis at the beginning of cell division, the nuclear envelope fragments into vesicles. At the end of mitosis, after the two daughter cells have separated, these membrane vesicles bind to the decondensing chromatin and then fuse together laterally to re-form an intact nuclear envelope. RanGTP is essential for this fusion step, as is one particular nuclear carrier of the karyopherin- β family (importin- β), however, the exact mechanism is not yet known.

replication of chromatin during S phase and in regulation of kinetochore function throughout the cell cycle. It should be noted that in all of the multiple pathways in which Ran has been implicated, the general nature of the biochemical reaction carried out by Ran remains constant. Switching between RanGDP and RanGTP controls Ran's association with different proteins, and Ran's association with assorted proteins has different downstream effects depending on the protein involved, the cellular location where the interaction occurs, and the stage of the cell cycle when the interaction occurs. In summary, the Ran GTPase plays a powerful and irreplaceable role in the eukaryotic cell, both for constitutive viability and for cell division.

Other Roles of Ran

In addition to the cellular roles for Ran discussed above, Ran has also very recently been implicated in prevention of re-

Glossary

Effector Proteins (typically enzymes) that guanosine triphosphate (GTP)-bound Ras proteins bind to elicit a biological response.

GTPase Describes the intrinsic GTP hydrolyzing enzymatic activity of Ras. Binds guanosine diphosphate (GDP) or GTP with high affinity and catalyzes the hydrolysis of GTP to GDP and phosphate.

GTPase-activating proteins (GAPs) Negative regulators of Ras that bind the GTPase and accelerate its ability to hydrolyze bound GTP.

Guanine-nucleotide-exchange factors Upstream positive regulators of Ras proteins that promote increased nucleotide release so that Ras can bind to GTP.

Isoprenylation Process of irreversible posttranslational covalent modification of the C terminus of proteins by 15 carbon farnesyl or 20 carbon geranylgeranyl isoprene-derived lipids.

Ras A high-affinity guanine-nucleotide-binding protein with intrinsic GTPase activity that acts as a molecular switch or biotimer by cycling between inactive GDP- and active GTP-bound states.

Physical Properties

Ras family proteins are often referred to as small or low-molecular-weight guanosine triphosphatases (GTPases). This is due to their 20–25-kDa size being smaller than the 38–52-kDa α -subunits of the heterotrimeric G proteins, another class of cell-signaling molecules that bind and hydrolyze GTP. Ras proteins consist of a core GTP-binding/GTPase domain that encompasses ~160 amino acids, followed by a hypervariable domain that is thought to act as a flexible linker, and a C-terminal CAAX (cysteine-aliphatic-aliphatic-other amino acid) motif that is the signal for posttranslational lipid modification, see [Figure 1](#). Addition of a 15-carbon farnesyl or 20-carbon geranylgeranyl isoprene group to the Cys, cleavage of the three C-terminal (AAX) residues, and methylation of the C-terminal COO-group help promote the membrane targeting of most Ras subfamily GTPases. Additional palmitoylation of nearby cysteine(s) or presence of many basic (arginine and lysine) residues in the hypervariable region helps maintain tight membrane association. Membrane association is essential for Ras protein function and mutation of the CAAX cysteine, preventing the series of posttranslational modifications, disables Ras function. Most Ras superfamily proteins are modified by a geranylgeranyl transferase that adds the 20-carbon lipid. However, H-, K-, and N-Ras are modified by a farnesyl transferase that recognizes a different CAAX sequence that adds a 15-carbon farnesyl lipid instead. Most commonly, a serine or methionine in the X position signals for farnesylation of the CAAX, whereas leucine or phenylalanine signals for geranylgeranylation. Because of this specificity, drugs that mimic the C terminus of Ras and/or the farnesyl lipid can block posttranslational modification and clinical trials have been performed to evaluate their use in cancer chemotherapy.

The GDP/GTP Cycle and Ras Mutations

Ras binds GTP and guanosine diphosphate (GDP), but not guanosine monophosphate, with very high affinity. The intrinsic rates of nucleotide exchange and GTP hydrolysis

by Ras *in vitro* are very slow (on the order of minutes to hours) and not practical for a signaling molecule that needs to rapidly respond to incoming stimuli. However, this is by design. Most Ras proteins are tightly regulated by one or more guanine-nucleotide-exchange factors (GEFs) that help turn it on and GTPase-activating proteins (GAPs) that subsequently help to inactivate it, see [Figure 2](#).

Ras GEFs contain a CDC25 homology domain that shares similarity with the yeast RAS1/2 GEF, CDC25 (not to be confused with the mammalian Cdc25 protein phosphatase). There are over 30 CDC25 homologs in the human genome. Some are highly specific for one Ras protein, while others catalyze nucleotide exchange and multiple family members. GEFs promote the release of GDP, then stabilize the nucleotide-free protein until GTP can subsequently bind and displace them. This occurs very rapidly *in vivo* due to the high affinity of Ras for GTP. Also because GTP is in a 10–20-fold excess over GDP, the GEF is predominantly displaced by GTP. Because of the ability of nucleotide-free Ras to bind tightly to GEFs, dominant inhibitory mutants have been designed that have low affinity for nucleotide. These bind tightly to GEFs and prevent them from activating the endogenous wild-type Ras, so blocking signaling pathways. These are useful tools for implicating Ras proteins or Ras pathways in the control of cellular events. The most commonly used is a serine to asparagine mutation of H-Ras residue 17 (H-Ras17N).

Although Ras is a GTPase, it has a poorly designed catalytic site. However, GAPs help stabilize the catalytic site and contribute a critical arginine residue that greatly accelerated nucleophilic attack of the GTP. One reason the α -subunits of heterotrimeric G proteins are bigger than Ras proteins is that they have an extra domain that contributes an 'arginine finger' resulting in their typically having a higher intrinsic GTPase activity than Ras. Mutations that block intrinsic and GAP-stimulated GTP hydrolysis result in Ras proteins being locked in their active GTP-bound state. Such mutations at residues 12, 13, and 61 are found in H-, K-, or N-Ras in various human tumors. Ras subfamily GAPs fall into two structurally distinct families; those that regulate Rap/Rheb and those that

Figure 1 Linear diagram of Ras protein highlighting key sequences. Light-blue areas are highly conserved across the entire Ras superfamily and form the guanine-nucleotide-binding pocket. Closed circles indicate sites of activating mutations found in human cancers. Switch I and II domains change conformation upon GDP vs. GTP binding. E, effector binding loop that associated with downstream effectors; H, hypervariable domain, a 10–20-amino-acid linker that also contributes to membrane and target protein binding; CAAX, the terminal four residues that signal for posttranslational lipid modification of the cysteine residue. The identity of residue X dictates whether the G protein receives a 15- or 20-carbon lipid tail.

Figure 2 GDP/GTP-cycle activity of Ras family GTPases. Ligand binding induces receptor-mediated activation or membrane-recruitment of guanine-nucleotide-exchange factors (GEFs) which promote the release of GDP from Ras and acquisition of GTP from the cytosol. GTP binding promotes a conformational change permitting Ras to associate with downstream effector proteins to elicit a biological response. GTPase-activating proteins (GAPs) also recognize Ras-GTP and their binding promotes rapid acceleration of Ras' intrinsic GTPase activity. This converts Ras back to its inactive GDP-bound state from which the cycle can begin again. Mutations that block the intrinsic and GAP-stimulated GTPase activity lock Ras in its active, GTP-bound state.

regulate Ras and other GTPases. One of the Ras GAPs, neurofibromin, is the product of the NF1 tumor suppressor and, upon its loss, Ras GTP levels become elevated contributing to increased signaling that results in cancer and other proliferative diseases. Information on the better-characterized Ras subfamily members is provided below.

H-, K-, and N-Ras

H-, K-, and N-Ras represent the original and best-studied/-understood Ras proteins. Mutations of each of these proteins are found in human tumors with those in K-Ras being the most prevalent. K-Ras can have alternate splicing of its fourth exon with the '2' or 'exon 4B' version being the most predominant.

It was long known that Ras is involved in growth control downstream of growth factor receptors, and in 1993, an entire

pathway from cell-surface receptor to the nucleus was delineated. The binding of growth factors to their protein tyrosine kinase receptors leads to phosphorylation of the receptors on tyrosine residues. This enables the binding of various adapter proteins that contain modular Src homology 2 or SH2 domains that recognize specific primary sequences that contain phospho-tyrosine. One such molecule is Grb2 that also has two SH3 domains that bind to proline-rich sequences like those found in the Ras GEF, Sos. Binding of a preformed Grb2–Sos complex to receptor tyrosine kinase results in recruitment of Sos to the plasma membrane where it promotes GTP loading of Ras. In its active GTP-bound state, Ras now adopts a conformation that enables it to bind to the serine/threonine protein kinase, Raf. This, in turn, recruits Raf to the membrane, promotes a conformational change, and enables Raf to be phosphorylated by nearby kinase(s). Raf then phosphorylates MEK, which phosphorylates extracellular signal-regulated kinases (ERKs) 1 and 2. Phospho-ERKs translocate into the nucleus where they phosphorylate transcription factors such as Elk1, leading to increased gene expression. It is now known that a number of additional signals activate Ras. For example, Ras GEFs (such as GRF1 in brain and GRP1 in T cells) and GAPs (Capri, Rasal) can be activated by Ca^{2+} elevation and/or diacylglycerol. Additionally, G-protein-coupled receptors can trigger tyrosine phosphorylation to regulate the Grb2/Sos complex.

Growth factor receptors reside on the plasma membrane and Ras also localizes there. However, Ras is also found on the Golgi membrane and many of the events mediated by Ras occur at this intracellular site. One mechanism whereby activation of cell-surface receptors might signal to Ras at a remote intracellular membrane is via Ca^{2+} elevation, resulting in the activation of a Ca^{2+} -regulated exchange factor, as has been reported in T cells.

Binding of GTP triggers a conformational change in Ras in two regions called switch I and II. Switch I, which encompasses residues ~32–40 is the main determinant for effector binding. Conformation of this and switch II dictate which targets various Ras subfamily members associate with. Although a number of putative Ras effectors have been described, three have been particularly well characterized. These are the protein kinase Raf, phosphatidylinositol 3 kinase (PI3K), and RalGDS, an exchange factor for the Ras-related GTPase, Ral (see below). There are several isoforms of each of these effectors that have different tissue distribution and affinities for various Ras family members. However, each

of these effectors has a related ~60-residue Ras association (RA) or Ras-binding domain (RBD). As RBD/RA domains bind specifically to Ras-GTP, the isolated domains (typically fused to glutathione S-transferase and immobilized on glutathione-conjugated beads) can be used in the lab to precipitate Ras-GTP from cell lysates to gauge intracellular Ras activity. The Raf RBD is typically used to detect H-, K-, or N-Ras activity. Although most Ras activity is associated with increasing cell growth and transformation, several recently characterized Ras targets that include RASSF1 appear to have tumor-suppressing properties.

Ral

As indicated above, a family of four Ral GEFs (RalGDS, Rgl, Rgl2/Rlf, Rgl3/RPM) possess RBDs and are downstream effectors of Ras. The primary function of Ras here is in recruiting Ral-GEFs to the membrane where they can activate Ral. In addition to being regulated by Ras/RalGDS, Ral is activated by Ca^{2+} , possibly due to its ability to bind calmodulin and by a second class of GEFs (the RalGPS family) that lack an RA domain/Ras regulation.

Due to its regulation by Ras, initial studies on Ral focused on its ability to regulate tumorigenesis, and RalGDS has been established as an important mediator of Ras-induced transformation of human epithelial cells. Ral or its GEFs have been reported to regulate various transcription factors including c-Fos, c-Jun, STAT3, and AFX (a member of the forkhead family). Interestingly, Ral-GEFs are often more potent at inducing biological effects than activated (GTPase-defective) Ral mutants. This may be because (1) GTP/GDP cycling is required for Ral function or that (2) RalA and RalB act in concert to promote their biological effects. Depletion of RalA severely impairs the anchorage-independent proliferation of cancer cell lines, whereas RalB seems to be essential for the survival of a variety of tumor-derived cell lines as well as their ability to metastasize. Thus, RalA and RalB appear to cooperate to drive oncogenic transformation.

Ral proteins localize to intracellular vesicles in both endocytic and exocytic compartments and regulate the exocyst, a protein complex that directs vectorial targeting of vesicles from the Golgi to the basolateral membrane of epithelial cells. Ral is essential for this process in higher eukaryotes but, puzzlingly, Ral is not present in yeast where the exocyst was first identified. The ability of RalA to promote the movement of lipid rafts (cholesterol- and sphingolipid-rich membranes replete with key signaling molecules) to the plasma membrane is likely key to its ability to promote anchorage-independent growth. RalB also drives exocyst assembly during polarized cell migration. This along with its ability to increase the transcription of a survival factor, FLIP, contribute to its key role during tumor metastasis. The Ral proteins also regulate receptor-mediated endocytosis but this is achieved via a distinct effector, RalBP1/RLIP76. RalBP1 not only binds to proteins associated with endocytosis but also contains a GAP-like domain for the Rho family GTPase, CDC42. It is via this activity that it may also regulate cell morphology. Given these myriad functions, it is not surprising that Ral proteins can contribute to cell proliferation and cancer.

R-Ras 1, 2, and 3

R-Ras, TC21 (R-Ras2), and M-Ras (R-Ras3) are closely related to Ras (**Figure 3**) and have overlapping signaling and biological functions. However, despite the transforming activity of laboratory-engineered mutants and the identification of a few activating mutations in cultured cell lines, these GTPases appear to seldom be mutated in human cancers. R-Ras activates PI3K but does not regulate the Raf/ERK or RalGDS pathways. Distinct from H-Ras, R-Ras has been implicated in 'inside-out' signaling, increasing the ability of integrins to bind extracellular matrix. This enhancement of receptor-ligand binding results in increased cell attachment and spreading. One study has implicated Rap1 as a mediator of R-Ras action, whereas others show a requirement for the Rho family GTP-binding protein Rnd for R-Ras inactivation, two more examples of Ras protein cascades. Complexes of semaphorins and plexins that play important roles in development and axon guidance regulate R-Ras and orchestrate growth cone collapse.

Like R-Ras, TC21 and M-Ras also effectively activate PI3K. TC21 was recently implicated in the survival and proliferation of T and B cells via direct interaction with antigen receptors. Although M-Ras is most abundant in brain, its exact function is unclear. Despite preferentially activating PI3K, M-Ras can also impact Raf activation by regulation of its phosphorylation state.

Rap1 and 2

There are five members of the Rap cluster: Rap1A and 1B and Rap2A, 2B, and 2C of which Rap1A/B function is best understood. Rap1A/Krev-1 was isolated in 1988 due to sequence homology with Ras (Ras-proximate) and also due to its ability to revert the transforming activity of K-Ras. The revertant activity was believed due to Rap1A binding to Ras effectors and acting as a competitive antagonist of Ras. This indeed may occur in T cells where Rap needs to be turned off by a costimulatory receptor such as CD28 in order for T-cell receptor-induced activation of Ras to have its desired effect. However, the main role of Rap1 appears to be in the inside-out regulation of integrins. A Rap1 effector RAPL has recently been described in leukocytes, which is responsible for promoting integrin clustering but how Rap regulated adhesion of cells in solid tissues is still not fully understood. Although early studies described Rap1 and 2 localization to endocytic and Golgi membranes, Rap1 also localizes to epithelial and endothelial cell adherens junctions where it plays a role in junction maintenance. It is likely that Rap1 and 2 plays multiple cell type-specific roles.

Rap1 and 2 are regulated by the same GEFs and GAPs. Strikingly, at least 10 of the CDC25 family as well as the unrelated Smg GDS and DOCK4 proteins act as Rap GEFs suggesting that Raps play fundamental roles in cell biology that are triggered by a broad spectrum of extracellular stimuli. Signals from Ca^{2+} , diacylglycerol, cyclic adenosine monophosphate (cAMP), as well as receptor and nonreceptor protein tyrosine kinases can all activate Rap. Indeed the protein kinase A-independent effects of cAMP are due to activation of two Rap GEFs, Epac1 and 2, that contain cyclic nucleotide-binding

Figure 3 Dendrogram showing relatedness of mammalian Ras subfamily proteins. Commonly used names in literature are included as well as official gene names.

domains. Several Rap GEFs also contain RA domains, and are recruited to membranes as downstream effector of other GTPases. This suggests that Rap activation may be a requisite for other Ras family members to execute their biological functions. Rap1a and 1b null mice as well as work using small interfering (si) RNA have recently implicated Rap1 in endothelial cell adherens junction formation, angiogenesis, and a variety of leukocyte functions.

Rheb

Despite its name, Rheb (Ras homolog expressed in brain) is found in many tissues. However, it was discovered in 1995 as a

protein whose expression was induced by synaptic stimulation. Although no Rheb GEFs have been found to date, Rheb's GTPase activity is regulated by TSC2/tuberin, a tumor-suppressor protein whose C terminus resembles that of Rap GAPs. Following loss of TSC2 or mutation of its GAP domain, the loss of GAP activity results in the accumulation of Rheb GTP. This activates the mammalian target of rapamycin, mTOR, a kinase that stimulates protein synthesis in response to growth factors and nutrient abundance. Interestingly, Rheb is posttranslationally farnesylated similarly to H-, K-, and N-Ras. However, the use of farnesyl transferase inhibitors to block mTOR activation as a result of Rheb activation downstream of various tumor-suppressor proteins (TSC1, TSC2, PTEN, NF1, or LKB1) has not proved successful.

Other Ras Family Members

A number of additional GTPases exist (Figure 3) that are less well characterized but help exemplify the diversity of GTPase functions. These include the ARHI/DiRas and Rerg/RasL11 families that have each been shown to play inhibitory roles, the latter being suppressed in breast and prostate cancers, respectively. Critical conserved residues within their GTP-binding pockets diverge from those of most other Ras family members suggesting that these G proteins are constitutively GTP bound. The expression of these proteins can be regulated by various agonists suggesting that they are regulated at the level of gene expression rather than by GEFs and GAPs. Further, it is often their loss rather than mutation that contributes to cellular proliferation/transformation. Transcriptional regulation is not limited to these proteins; for example, RasD1/Dex-Ras expression is induced by corticosteroids, RasD2/Rhes by thyroid hormone and Rheb by estrogen and, as noted above, synaptic stimulation. Another branch of the Ras subfamily regulates transcription: NKIRas1/2 bind to the nuclear factor κ B/inhibitor of NF κ B (NF κ B/I κ B) complex and help mask a nuclear localization sequence so that this transcription factor complex cannot translocate to the nucleus and induce gene expression.

The function of the RGK branch of the Ras family (Rem1 and 2, Rad, and Gem/Kir) has until recently eluded investigators. However, they have now been shown to negatively regulate the Rho–Rho kinase pathway, helping to explain their ability to modulate the actin cytoskeleton. Additionally, they interact with and regulate voltage-dependent calcium channels.

Finally, several Ras family proteins lack the characteristic C-terminal CAAX box required for posttranslational lipid modification. These include the closely related Rit and Rin proteins as well as Rerg and NKIRas. Although the former two proteins have been reported to regulate PC12 (pheochromocytoma) cell differentiation, an event regulated by several Ras proteins via Raf and/or PI3K, Rit, and Rin appear to act via some alternative pathway(s). Interestingly, although Rit lacks any

known recognition signal for C-terminal lipid modification, proliferation and survival of Rit-transformed cells in low-serum growth medium is dependent on a farnesylated protein. As most prenylated proteins are G proteins, this suggests, once again, the possibility of cross talk between members of the Ras subfamily of GTPases exists.

Glossary

Electron transport chain The site of oxidative phosphorylation in the mitochondrial inner membrane which couples the transfer of electrons from electron donors (such as NADH) to O₂ with the pumping of protons (H⁺) from the matrix to the intermembrane space, thus generating an electrochemical proton gradient which is used by adenosine triphosphate (ATP) synthase to produce ATP.

Flavin The prosthetic group in flavoproteins which is capable of undergoing oxidation–reduction reactions by accepting/donating either one or two electrons at once.

Heme The prosthetic group in hemoproteins which contains an iron atom at the center of a porphyrin ring and serves various roles, such as a source/sink of electrons during electron transport and redox reactions and the transportation of diatomic gases.

Iron–sulfur center Moiety in iron–sulfur proteins, often consisting of four iron atoms and four sulfur atoms arranged in a cubane-like structure, which participates in redox reactions, particularly in mitochondrial electron transport.

Krebs cycle Series of enzyme-catalyzed reactions occurring in the mitochondrial matrix which uses acetyl-coenzyme (CoA) and oxaloacetate to reduce three NAD⁺ to NADH and one Q to QH₂, while also producing one GTP and two CO₂.

Oxidative stress State in which there is an increase in oxidizing species, such as reactive oxygen species (ROS), and/or a decrease in antioxidant defenses, and often leads to protein, lipid, and DNA damage.

Redox center Moiety which is either oxidized or reduced during redox reactions (e.g., flavins, iron–sulfur centers, and hemes).

Reductive stress State of redox imbalance in which there is an excess in reducing species, leading to a reductive cytosolic environment (e.g., high NADH:NAD⁺ ratio).

Thiols Organosulfur compound containing a carbon-bound sulfhydryl group (e.g., cysteine and glutathione) which participates in redox biology and signaling through the formation of various oxidation states.

Introduction

The importance of reactive oxygen and nitrogen species (ROS/RNS) in physiology, as well as in pathology, and their interactions with mitochondria are well established. Originally, ROS/RNS were considered to be simply destructive and cytotoxic, but more recently it has become clear that they have several beneficial effects through their ability to activate specific cell-signaling pathways. ROS have been shown, at low levels, to induce cell proliferation and control the synthesis of endogenous antioxidant enzymes. Mitochondria are both a source and target for ROS and play a key role in redox cell signaling. Under pathological conditions, increased levels of mitochondrial ROS formation can lead to damage to DNA, lipids, and proteins. This can impair bioenergetic function, and, in some cases, initiate programmed cell death or apoptosis (Figure 1).

Nitric oxide (•NO) is the best-understood redox signaling molecule. It modulates cell function through its interaction with heme proteins such as soluble guanylate cyclase, cytochrome *c* oxidase, and hemoglobin. In addition, •NO can lead to protein modification through its ability to interact with ROS leading to S-nitros(yl)ation or oxidation. On the other hand, the reactions of ROS and RNS have been implicated in many chronic pathologies, particularly those involving inflammation. For example, high levels of reactive species have been shown to further the progression of various cardiovascular and neurodegenerative diseases.

Nitric oxide is produced by a family of enzymes called the nitric oxide synthases (NOSs) and mediates its cell signaling effects through protein modification and binding to heme iron. Despite its predominantly extra-mitochondrial origin, •NO is also known to modulate mitochondrial function at cytochrome *c* oxidase and to stimulate mitochondrial biogenesis by activation of soluble guanylate cyclase. The aim of this chapter is to discuss what reactive oxygen and nitrogen species are, how they are formed, and how they interact with the mitochondrion and give key examples of their biological effects in cardiovascular and neurodegenerative pathologies.

What Are Reactive Oxygen and Nitrogen Species?

The terms ROS/RNS are freely used in the biological literature; however, it is important to note that they do not have a specific chemical definition and may include free radicals and nonradical species. The general property they all share is that ROS/RNS react with biological molecules leading to changes in function that may contribute to cell signaling in a controlled fashion or to the pathology of a disease. It seems likely that the modification of protein cysteine residues is the basis of redox cell signaling and can be highly specific. In contrast, nonspecific oxidation reactions such as carbonylation are generally thought to contribute to protein damage, aggregation, and activation of the autophagic process.

Figure 1 Effects of mitochondrial ROS. Mitochondrial ROS production can alter the function through a variety of pathways. Lower levels of ROS can act through several redox signaling mechanisms, while higher levels can directly damage mitochondrial proteins, leading to the further production of ROS. ROS can also damage mtDNA and induce lipid peroxidation in the membrane, and can also cause mitochondrial permeability transition pore (mPTP) opening, which leads to cytochrome *c* release and apoptosis induction.

Reactive Oxygen Species

The ROS are the partially reduced intermediates of oxygen and can be radical or nonradical molecules. Free radicals are denoted in a chemical formula using a superscript dot which is usually written next to the symbol of the atom which carries the unpaired electron. ROS include the superoxide radical anion (O₂^{•-}) and its protonated form, the hydroperoxyl radical (HO₂[•]), hydrogen peroxide (H₂O₂), and the hydroxyl radical (•OH). As discussed below, O₂^{•-} is formed by the mitochondrial respiratory chain at a number of sites within electron transport and the Krebs cycle. As the mitochondrion contains high levels of the enzyme superoxide dismutase (SOD), most of the O₂^{•-} that is formed is converted into H₂O₂.

Reactive Nitrogen Species

As with reactive oxygen species, this is a term commonly used by biologists to describe •NO-derived molecules which show biological activity. Nitric oxide is an uncharged free radical which can diffuse freely across membranes. It reacts rapidly with other free radicals and has a high affinity for ferrous heme groups. The RNS peroxynitrite (ONOOH) is formed from the reaction of superoxide with •NO and has been studied in depth. The reactivity of peroxynitrite is enhanced in biological systems through its reaction with carbon dioxide to form nitrosoperoxycarbonate, which can then undergo homolytic fission to generate the nitrogen dioxide (NO₂[•]) and carbonate

(CO₃^{•-}) radicals, both of which are reactive and can cause damage to biomolecules. For example, NO₂[•] can react with tyrosine residues or tyrosyl radicals on proteins, resulting in 3-nitrotyrosine formation. This adduct can be detected in a broad range of pathologies, and is often used as a marker of nitrative stress. Nitrated proteins have been detected in mitochondria isolated from a broad range of pathological conditions. Mitochondrial DNA damage is associated with several diseases associated with oxidative and nitrative stress, leading to increased mitochondrial ROS production and dysfunction.

Generation of ROS from Mitochondria

Mitochondria can generate ROS from a number of different redox centers in several metabolic pathways. The basic principle for ROS generation from these sites is shown in [Figure 2\(a\)](#). Electrons are transferred to a redox center which then acts as an intermediate carrier to another redox active member of the metabolic pathway. The more reduced the redox center is, the greater the potential production of ROS. The detailed mechanisms for ROS generation from each redox center are described below.

Complex I

NADH-ubiquinone oxidoreductase (complex I) consists of 45 subunits with a combined mass of close to 1 MDa. Complex I accepts two electrons from NADH, which is produced by the

Figure 2 Mechanisms of ROS formation in the mitochondria. The sites of ROS production within the mitochondria all follow a similar mechanism. An electron donor donates an electron to a redox center, which then reduces the electron acceptor. However, electrons can also be transferred from the redox center to reduce oxygen into superoxide (a). Complex I oxidizes NADH through the FMN site, and can transfer the electrons to either the CoQ site to make ubiquinol (QH_2) or, if the CoQ site is inhibited, to O_2 to make superoxide (b). In reverse electron transport (RET), QH_2 produced by complex II can be transferred back into complex I through the CoQ site to the FMN, which can then either reduce NAD^+ back to NADH or reduce O_2 to form superoxide (c). Complex III uses QH_2 produced predominantly by complex I and II as the electron donor, transferring the electrons to the Rieske Fe-S and then on to cytochrome c1 and finally cytochrome c. Complex III also transfers electrons to the b_L heme, which participates in the Q cycle. However, when the Q cycle is inhibited, by antimycin A, for example, the electrons can leak out of the Q_o site to reduce O_2 to make superoxide (d). Complex II has also been shown to produce superoxide when electron transfer to the CoQ site is inhibited, or when the enzyme is solubilized, causing electrons to leak from the reduced FAD site to make superoxide (e). PDH and α KGDH use their substrates to transfer electrons through their E3 subunit to reduce NAD^+ ; however, electrons have also been shown to reduce O_2 to make ROS (f). EFT-QOR oxidizes EFT and transfers electrons through its FAD domain to reduce Q to QH_2 , but it has also been shown that it can also reduce O_2 to superoxide as well (g). GPDH reduces G3P via its FAD site to make QH_2 , although it has also been shown to leak electrons to make ROS as well (h).

Krebs cycle, via a flavin mononucleotide (FMN) and transfers them through a chain of seven iron-sulfur centers to the CoQ reduction site. There the electrons are transferred to the lipid-soluble electron carrier ubiquinone (Q), reducing it to ubiquinol (QH_2). One mechanism by which complex I produces ROS is by the reaction of O_2 with the fully reduced FMN

forming $O_2^{\bullet-}$ on the matrix side of the complex. The rate of $O_2^{\bullet-}$ production at the FMN can be increased by inhibiting the CoQ site using the small molecule inhibitor rotenone. Similarly, this reaction is dependent on the NADH/ NAD^+ ratio, which determines the proportion of FMN that is fully reduced. Under physiological conditions, $O_2^{\bullet-}$ generation

from complex I is sensitive to the redox state of the respiratory chain (Figure 2(b)).

Pathologically, there are several conditions which result in a reductive stress, causing the NADH/NAD⁺ ratio to increase, and this in turn results in increased O₂^{•−} production. Some of the best-understood examples of this condition are the reductive stresses associated with alcohol metabolism and ischemia.

An additional mechanism through which complex I can produce ROS is called reverse electron transport (RET) (Figure 2(c)). This occurs when the mitochondria are utilizing succinate as a substrate through complex II. Under conditions of low electron flux (when adenosine diphosphate (ADP) levels are low), the larger pool of reduced QH₂ is sufficient to reduce complex I at the CoQ site. This reverses the normal flow of electrons back through the complex to reduce the FMN site, thereby reducing NAD⁺ to form NADH, while also reducing O₂ to form O₂^{•−}. RET results in the generation of O₂^{•−} in the matrix and can be inhibited with rotenone treatment. Interestingly, RET generates the highest rate of O₂^{•−} formation detected thus far in the mitochondrion. Whether RET plays a physiological role in cell signaling through ROS is not clear.

Since complex I appears to play a central role in mitochondrial ROS formation, it is not surprising that it has been implicated in a number of pathological processes. For example, the complex I (and RET) inhibitor rotenone has been shown to induce Parkinson's disease-related pathologies in rodents. It may also be an important environmental toxicant which can contribute to Parkinson's disease pathogenesis in humans. Furthermore, many studies have consistently found decreases in complex I activity in Parkinson's disease brains. Other compounds have been shown to interact with complex I, modifying both enzyme activity and ROS formation. An important example is 1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine (MPTP), originally discovered as a by-product of illegal heroin production, which was shown to cause Parkinsonism in drug users. MPTP toxicity is mediated by its metabolite MPP⁺, which is selectively taken up by dopaminergic neurons and inhibits complex I activity, leading to their eventual death.

Complex III

Complex III is approximately 240 kDa and is made up of 11 subunits, three heme groups, and the Rieske iron-sulfur (Fe-S) center. It functions by oxidizing QH₂ in the inner membrane and transferring the electrons to reduce cytochrome *c* in the intermembrane space. The rates of O₂^{•−} production from complex III are relatively low during RET compared to that of complex I. However, the further inhibition of complex III with the Q_o site inhibitor myxothiazol attenuates most of this O₂^{•−} production, which suggests that complex III does produce some O₂^{•−} during RET, albeit a small amount. Alternatively, when the Q_i site is inhibited using antimycin A, complex III produces greater amounts of O₂^{•−}, which are released to both sides of the inner membrane. This formation of O₂^{•−} is due to the reaction of O₂ with the QH bound to the Q_o site. This O₂^{•−} formation due to antimycin A can be abrogated by treatment with myxothiazol, which inhibits the Q_o site, suggesting that QH bound to the Q_o site is the main site of O₂^{•−} production (Figure 2(d)).

Complex II

Succinate dehydrogenase, also known as complex II, is embedded in the matrix side of the inner mitochondrial membrane and consists of four subunits. It contains a flavin adenine dinucleotide (FAD) site, three Fe-S clusters, a heme group, and a Q binding site. Complex II oxidizes succinate to fumarate as part of the Krebs cycle, which is coupled to the reduction of Q to QH₂. Complex II readily produces O₂^{•−} when solubilized, probably by the reaction of O₂ with the reduced FAD site, due to the lack of Q as an electron acceptor (Figure 2(e)). This can occur *in vivo*, and only when complex II has been damaged by oxidative stress or aging. There are also several genetic mutations of the various subunits of complex II which can cause increased O₂^{•−} production. Several of these mutations have been shown to lead to cancer, particularly cancers of neuroendocrine lineage. However, complex II produces very little O₂^{•−} during normal physiological conditions.

Other Sources of ROS Formation within the Mitochondrion

Other mitochondrial metabolic pathways, including the Krebs cycle, contain proteins with redox centers which are also capable of generating ROS. For example, the enzyme glycerol-3-phosphate dehydrogenase (GPDH) has been shown to produce O₂^{•−}. This enzyme participates in the glycerol-3-phosphate (G3P) shuttle, which provides a mechanism for the transport of electrons from cytosolic NADH to the electron transport chain, by oxidizing NADH on the cytosolic face of the outer mitochondrial membrane and reducing Q to QH₂ in the inner mitochondrial membrane. GPDH has been reported to have some G3P-dependent production of O₂^{•−}, most likely at the FAD site within the enzyme (Figure 2(h)). Approximately 70% of the O₂^{•−} produced is directed to the intermembrane space, while 30% is directed toward the matrix.

Similarly, α -ketoglutarate dehydrogenase (α KGDH), which is responsible for the conversion of α -ketoglutarate to succinyl CoA in a reaction which is coupled to the reduction of NAD⁺ to NADH, can generate O₂^{•−} when the NADH/NAD⁺ ratio is elevated. This occurs in the E3 subunit of the enzyme complex, which is a flavoprotein known as dihydrolipoamide dehydrogenase (DLD). Pyruvate dehydrogenase (PDH) has been shown to produce ROS via a similar mechanism (Figure 2(f)).

In addition, many of the key enzymes controlling fatty acid oxidation are located in the mitochondrial matrix and inner membrane. In this metabolic pathway, reduction of the electron transfer flavoprotein (ETF) results in the conversion of Q to QH₂ via the enzyme ETF:ubiquinone oxidoreductase (ETF-QOR). ETF-QOR is located on the mitochondrial inner membrane and contains an Fe-S cluster and an FAD site, and has been shown to produce O₂^{•−} directed toward the matrix when in the presence of palmitoyl carnitine as a substrate. ETF-QOR has also been shown to increase RET and so can enhance O₂^{•−} production from complex I (Figure 2(g)).

Can the Mitochondria Sense the Site of ROS Formation?

If mitochondrial ROS play a role in cell signaling, it implies that the site of ROS formation within the respiratory chain will lead to differential modification of mitochondrial proteins.

This is a relatively new concept, but in support of this idea it has been shown that ROS produced by complex III upon treatment with antimycin A induces the modification of protein thiols on complex III core protein I, which does not occur with exogenous hydrogen peroxide treatment or with the induction of RET. These modifications are reversible by the peroxiredoxin/thioredoxin system, as well as by glutathione, which further support their roles as mediators of redox signaling. Reversible thiol modification due to ROS production by specific respiratory chain complexes may be responsible for regulation of carbohydrate and fatty acid metabolism. Mitochondrial protein thiols may be more susceptible to modification than cytosolic protein thiols because of both the proximity to the source of ROS and the fact that the mitochondrial matrix has a high pH (~8), which will result in more thiols being in their reactive form, the thiolate anion.

Mitochondria have also been shown to sense ROS levels through cardiolipin oxidation. Cardiolipin is an abundant lipid which is found in the mitochondrial inner membrane. Cardiolipin participates in redox signaling due to its propensity for peroxidation in the presence of high levels of ROS. The peroxidation of cardiolipin then enables it to induce apoptosis by aiding in mitochondrial pore opening and cytochrome *c* release from the intermembrane space.

Can Mitochondrial ROS be Controlled?

The mitochondrion has several ways through which it can control the levels of ROS it produces. Superoxide can be converted to hydrogen peroxide by the enzyme SOD. The SOD located in the mitochondrial matrix contains a Mn prosthetic group and is known as SOD2 or MnSOD. The SOD located in the cytosol contains Cu/Zn prosthetic groups and is known as Cu/Zn SOD or SOD1. SOD1 may also be present in the mitochondrial inter-membrane space. SOD2 provides a major mechanism by which the mitochondrion can control the levels of ROS, through its ability to catalyze the dismutation of $O_2^{\bullet -}$ to hydrogen peroxide, which can be further metabolized to H_2O by peroxiredoxin, thioredoxin, or glutathione peroxidase. In addition, these systems can also help to remove other peroxides, such as those that have formed on lipids and proteins.

Mitochondria also control reactive oxygen species production through the ability of uncoupling proteins (UCPs) to increase proton leak and decrease the mitochondrial membrane potential and the redox state of sites of $O_2^{\bullet -}$ formation. UCP3 has also been suggested to lower mitochondrial levels of lipid peroxidation by causing fatty acid efflux out of the matrix when fatty acid levels are in excess.

Nitric Oxide and Mitochondria

Nitric oxide partitions into the mitochondrial inner membrane and inhibits cytochrome *c* oxidase by competing with O_2 for binding at the binuclear Cu_B /cytochrome a_3 site. $\bullet NO$ binding to complex IV is O_2 dependent, which may be beneficial because it can then allow O_2 to diffuse further into tissues, thus extending the O_2 gradient. However, excessive inhibition of mitochondrial respiration by $\bullet NO$ may lead to inhibition of

ATP formation and can be pathological. In addition to modulating mitochondrial function, low levels of $\bullet NO$ are now known to be able to induce mitochondrial biogenesis. This occurs through $\bullet NO$ activating soluble guanylate cyclase (sGC), which then produces cyclic GMP (cGMP). The cGMP then leads to the activation of PGC-1 α , which is the principal transcription regulator of mitochondrial biogenesis.

However, when $\bullet NO$ is produced in excess, it impacts on pathologies with an underlying bioenergetic defect, including ischemia reperfusion. One prominent example of $\bullet NO$ production in the central nervous system is associated with ischemic stroke. Initial brain damage is caused by lack of blood flow, oxygen, and nutrients. Further exacerbating the initial insult, injured ischemic brain cells release excitatory amino acids, such as glutamate, into the synapses between neurons. Excitatory amino acids bind to and induce over-excitation of neighboring neurons, leading to calcium influx. Both the primary ischemia itself and the secondary over-excitation of neighboring neurons followed by calcium influx induce NOS, resulting in overproduction of $\bullet NO$. The excessive $\bullet NO$ in neurons, in turn, causes DNA, protein, and organelle damage, and promotes additional cell death with a major contribution from mitochondrial calcium overload and bioenergetic failure.

Summary

In this short overview, we have outlined how ROS/RNS are formed as well as how they function in (patho)physiology. Although much is already known about the production and function of these reactive species, many aspects of how ROS and RNS are formed by and interact with the mitochondrion are still unclear, particularly *in vivo*. A greater understanding of how these species are formed, and how they affect mitochondrial and cellular function, is important for the development of mitochondrial therapeutics.

Glossary

Direct restart pathways Pathways that restart replication forks that are intact but have become stalled or blocked.

Gene conversion Nonreciprocal recombination event in which one allele is converted into the form of the second allele.

Homologous recombination Recombination between two nearly identical sequences that are not allelic (i.e., not at the same corresponding position on the chromosome).

Inducible stable DNA replication (iSDR) A pathway of recombination-dependent DNA replication in *Escherichia coli* that occurs without the normal initiator protein DnaA, but which does require recombination proteins (including RecA and RecBCD) as well as SOS induction.

Recombination-dependent replication (RDR) Extensive replication of a chromosome that is dependent on homologous genetic recombination and recombination proteins.

Recombinational restart The restart of broken replication forks by an RDR reaction.

Synthesis-dependent strand annealing (SDSA)

A double-strand break repair pathway in which one invading 3' end is extended by DNA polymerase using a homologous template; as the 3' end is extended, the newly synthesized strand at the back of the D-loop is extruded, and eventually pairs with the other broken 3' end to reattach the two broken ends to each other.

Early Models of Homologous Recombination Invoke Recombination-Dependent DNA Replication

One of the early molecular models for homologous recombination, called break-and-copy, invoked recombination-dependent DNA replication (RDR). One simple version of this model invoked a break in one molecule, with a resulting 3' broken end being used as primer for DNA replication. Another DNA molecule, of different parentage, is used as the template, resulting in a genetic crossover in the resulting DNA molecule.

As the field progressed, evidence accumulated in several systems for break-and-rejoin models without extensive DNA replication (but sometimes short gap filling reactions). Thus, break-and-copy models fell into disrepute for some time. We now understand that there are not only pathways of homologous recombination that do not involve extensive DNA replication, but also some very important recombination pathways that involve extensive DNA replication, as in the original break-and-copy models.

RDR Pathways in Bacteriophage

Most of the early data arguing for the existence of RDR came from studies of bacterial viruses. For example, recombination-deficient mutants of well-known bacteriophage such as T4, T7, and lambda were found to be partially defective in DNA replication. The interpretation of that replication defect was not straightforward, because recombination reactions can play indirect roles in viral DNA replication. For example, if recombination links multiple bacteriophage genomes together into a linear concatamer, a single initiation event from a conventional replication origin can result in much more DNA

replication than if the genomes are not linked. Furthermore, recombination proteins might play a role in converting a theta-form replication intermediate into a rolling circle, resulting in numerous replication products rather than just two.

Studies with bacteriophage T4, however, demonstrated that the involvement of homologous recombination proteins in DNA replication is very direct. At early times of infection, T4 DNA replication initiates at replication origins by a mechanism that involves a persistent RNA–DNA hybrid (R-loop), but this origin-dependent replication is turned off after several minutes. For the remainder of the infection cycle, all DNA replication initiates by an RDR mechanism in which a fully functional replication complex is assembled on a displacement loop (D-loop) (Figure 1). The D-loop is formed when the 3' single-stranded end of one phage DNA molecule invades a homologous region of another phage DNA molecule, or the other end of the same molecule (since T4 DNA is terminally redundant).

D-loop formation depends on the phage-encoded UvsX and UvsY proteins, acting in concert with the T4 single-stranded DNA binding protein gene product 32 (gp32). UvsX is a strand invasion protein, homologous to bacterial RecA and eukaryotic Rad51 protein, while UvsY plays the key role of loading UvsX onto gp32-coated single-stranded DNA (i.e., the 3' end).

Once a D-loop is formed, the phage protein gp59 is the critical component that directs the replication machinery to the D-loop. The gp59 protein preferentially binds branched DNA including D-loops and thereby stimulates the loading of the replicative helicase (gp41) onto D-loop substrates during *in vitro* replication reactions. Once the replicative helicase is loaded, more extensive template unwinding, loading of additional replication proteins, and extensive DNA replication becomes possible. Proteins that allow the loading of replicative helicases onto recombination intermediates are central to

Figure 1 Model for bacteriophage T4 RDR. A single-stranded 3' end is generated from a genomic end or break in the first step, either by exonuclease resection or by prior DNA replication up to the end (not shown in the figure). The strand invasion step creates a D-loop, upon which replication is initiated after assembly of the replication complex. The dotted lines indicate extended regions of the phage chromosome, and all newly replicated DNA is in red.

the process of RDR, and the corresponding bacterial proteins will be discussed below.

There is now quite convincing experimental evidence for the T4 RDR pathway. A variety of physical and genetic experiments support the proposal that genome ends trigger DNA replication after a strand-invasion reaction. Furthermore, artificially introduced double-strand breaks (DSBs) dramatically stimulate the replication of homologous DNA *in vivo*. Finally, a robust *in vitro* system of RDR has been established using the T4 system and recapitulates the major features of *in vivo* RDR.

RDR in *Escherichia coli* and Other Bacteria

An apparent cellular RDR pathway, called inducible stable DNA replication (iSDR), was first uncovered by the late Tokio Kogoma and colleagues. They found that *Escherichia coli* cells deficient in normal origin-directed replication could nonetheless replicate if their SOS system for DNA damage response was activated. This DNA replication required the strand invasion protein RecA, and a variety of results led to the proposal that iSDR also required chromosomal DNA breaks induced by some component of the SOS system. The simplest model is that the induced DNA breaks lead to invasive 3' ends, and that resulting D-loops become the sites of assembly of new replication complexes (much like in Figure 1). Experiments with artificially induced DSBs have directly shown that recombinational repair of breaks can indeed trigger DNA replication in *E. coli*, providing compelling support for bacterial RDR.

A key protein for *E. coli* RDR is PriA, which, like T4 gp59, allows the loading of the replicative helicase (DnaB in this case) onto D-loop structures. *In vitro* experiments have directly demonstrated PriA-dependent RDR on D-loops generated by the bacterial RecA and RecBCD proteins, using the normal replicative DNA polymerase III holoenzyme complex. Several other *E. coli* proteins, including DnaC, PriB, and PriC, also participate in PriA-dependent RDR reactions. The importance of PriA in the survival of *E. coli* will be discussed later, when we consider the role of RDR in completing genome replication. It is interesting to note at this point, however, that mutational inactivation of PriA dramatically reduces phage P1-mediated generalized transduction and also conjugal recombination. Therefore, these seemingly well-studied genetic pathways, which had been thought for decades to occur by a break-and-rejoin-like mechanism, may actually occur by a mechanism similar to RDR.

Homologs of the *E. coli* PriA protein are found in most bacterial species, indicating widespread occurrence of RDR in bacteria. The best-studied PriA homolog is from *Bacillus subtilis*, and like the *E. coli* protein, *B. subtilis* PriA plays a major role in loading the replicative helicase. Interestingly, the extremely radioresistant bacterial species *Deinococcus radiodurans* has no recognizable PriA homolog (but could have a functionally equivalent protein). Nonetheless, *D. radiodurans* can reconstitute its genome after very extensive levels of DNA breakage by a repetitive process that uses recombination to prime DNA synthesis, sequentially building up longer and longer segments of the genome from the broken pieces.

RDR in Eukaryotic Cells

RDR has also been convincingly demonstrated in eukaryotes, with the most direct studies in yeast model systems. Several different genetic approaches provided strong evidence that RDR is a legitimate pathway of DNA break repair in the yeast *Saccharomyces cerevisiae*. One approach used diploid yeast cells with a site that can be cleaved to create a DSB on one of the two copies of a particular chromosome, and the arms of this chromosome were marked with a series of heteroalleles (i.e., the two chromosomes had different genetic markers). Most DSBs were repaired by a localized event that did not alter the genetic markers on the remainder of the chromosome arm. At a low frequency, however, the resulting diploid cell experienced an extensive gene conversion event in which all alleles in the arm distal to the DSB had been converted to the form that was originally located on the unbroken (homologous) chromosome. Apparently, the distal chromosomal fragment from the broken chromosome had been lost and replaced with a newly replicated copy of the distal arm from the unbroken chromosome. When the experimental setup was altered so that the distal fragment of the broken chromosome had no homology to the intact chromosome, wild-type cells efficiently utilized this RDR pathway to regenerate an intact chromosome. The only general mechanism to explain this extensive gene conversion of a large portion of a chromosome is that the centromere-proximal chromosomal end undergoes a strand-invasion reaction with the homologous chromosome, and the resulting D-loop triggers a new replication fork just as in the RDR pathways.

Another informative genetic approach that reveals RDR in yeast involves the transformation of linear fragments of DNA with selectable markers and ends that are homologous to yeast chromosomes. In this case, a new chromosome can be established from the transforming fragment when one of the DNA ends invades the homologous chromosome and triggers an extensive RDR reaction that copies the homologous chromosome right to the telomeric end. In some experiments, both ends of the transforming fragment trigger RDR reactions, and in other experiments, one of the two ends is engineered to generate a new telomere upon transformation into the yeast cells (and so only one end needs to be repaired by RDR).

In addition to these compelling genetic approaches, direct physical assays have also been used to demonstrate RDR reactions in yeast and study their detailed characteristics. Furthermore, protein requirements for yeast RDR have been uncovered using one or more of the above assays. As might be expected, all three major replicative DNA polymerases are involved, as are the replicative helicase (MCM complex) and recombination proteins including RAD51, RAD52, RAD54, RAD55, and RAD57.

In vivo studies of RDR in cells from metazoans are more difficult than in the simpler model systems described above, but evidence is mounting that RDR is also important in mammals and other multicellular eukaryotes. In *Drosophila*, an RDR-related pathway called synthesis-dependent strand annealing (SDSA) is able to replicate extensive chromosomal regions (albeit with an unusual replication mechanism). Also, recent studies with chicken cells showed a provocative requirement for DNA polymerase η during immunoglobulin gene rearrangement by homologous recombination. In parallel, another group demonstrated that polymerase η can catalyze DNA replication from D-loops formed by human strand invasion proteins, arguing that η could be a key factor in triggering RDR from D-loops. As will be described in more detail below, genetic studies of mammalian cells deficient in certain recombination proteins lends support to the proposition that RDR is an important pathway for maintaining genome stability in higher eukaryotes, and RDR-related pathways likely contribute to chromosomal rearrangements (e.g., in the generation of cancer). Furthermore, biochemical studies with *Xenopus* oocyte extracts provide strong evidence that RDR provides a pathway for restarting stalled or aborted replication forks in that system (see below).

A special role for RDR has also emerged in the field of telomere biology, with important studies in both yeast and human systems. Human somatic cells generally lack telomerase and thereby acquire shorter and shorter telomeres with each cell doubling, until a crisis is reached. In order to propagate further, most human tumor cells reactivate telomerase to allow complete chromosome replication. However, a subset does not reactivate telomerase, and yet show strong telomere DNA replication – these are called ALT, for alternative lengthening of telomeres (ALT cells can also be obtained during immortalization of cell lines *in vitro*). Telomere replication in these ALT cells is dependent on recombination proteins and must occur by some form of RDR, although the detailed mechanism is not known. Likewise, prolonged growth of telomerase-negative yeast cells leads to progressive telomere shortening and a crisis period with short telomeres.

Many such cells rebound from the crisis by activating one or another telomere replication pathway that depends on recombination proteins. These and other findings have led to the suggestion that RDR may have been the primordial eukaryotic telomere replication pathway, with telomerase evolving later.

RDR as a Backup Mechanism to Complete DNA Replication

Nearly 30 years ago, Ann-Marie Skalka proposed that recombination could provide a mechanism for creating new replication forks after a previous fork encountered a template nick. Her proposal dealt with the complexities of phage lambda DNA replication, and was not ascribed any broader significance for some time. However, many years later, scientists realized that a similar mechanism provides a means of restarting a replication fork that has been destroyed by a template nick. As diagrammed in Figure 2, when a replication fork encounters a

Figure 2 Replication fork breakage at a nick and restart by recombination. A template nick leads to a broken fork, which is then restarted by RDR. Note that one DNA strand has been flipped to the top in the molecule immediately after the arrow indicating branch migration (because DNA is a double helix but the drawing depicts only parallel lines, this flipping is just a convenience to make the drawing simpler).

template nick, one of the two arms can be broken off and replication thereby terminated. The broken end can be reconfigured into a replication fork by first forming a D-loop using a strand-invasion reaction, and then assembling a replication complex onto the D-loop. Subsequent branch migration and junction resolution can thereby regenerate a simple replication fork and allow the completion of replication and normal segregation of the products at the next cell division (Figure 2).

We now believe that this pathway explains why many recombination-deficient mutants of bacteria grow poorly – they have great difficulty completing DNA replication due to problems at the fork. Notably, PriA-deficient mutants of *E. coli*, whose primary defect is in replication fork restart, are nearly inviable and quickly accumulate suppressor mutations that improve their viability.

In vivo experiments have demonstrated that replication forks are indeed broken when they encounter a template nick. It is not clear how often replication forks encounter template nicks, but broken replication forks also arise by another pathway that could be even more common. In bacterial and phage systems, it has been demonstrated that certain stalled or blocked replication forks are prone to breakage. This breakage can be induced by the branched-DNA-specific nucleases that normally resolve Holliday junctions (i.e., *E. coli* RuvC and T4 endonuclease VII). Results in eukaryotic systems also indicate that some blocked forks are broken in a similar manner.

It may seem strange that blocked replication forks would be actively cleaved by recombination nucleases, and this is indeed a dangerous reaction. However, this cleavage is apparently under strict control, and may only be used as a last resort when a stalled or blocked replication fork cannot be restarted by other mechanisms (see section [Replication Fork Failure and Direct Restart Pathways](#)). By coupling fork cleavage with an RDR reaction, the replication fork can potentially be restarted and the cell saved from the dire consequences that result from trying to segregate a partially replicated DNA molecule in the next cell division.

Xenopus oocyte extracts provide a powerful and convenient system to study many aspects of cellular biology, including DNA replication. Strikingly, when such extracts are depleted of the Mre11/Rad50/Nbs1 (MRN) complex, which is involved in homologous recombination and damage signaling, broken replication forks are generated and complete replication is prevented. Thus, in the normal extracts, the MRN complex is presumably contributing to restart of stalled and/or broken replication forks by an RDR pathway.

With this perspective that recombination provides a backup mechanism to restart broken replication forks, it is worth considering an interesting question from evolutionary biology – how and why did homologous recombination evolve? It is now clear that homologous recombination can play an important role at the level of single cell survival, namely the completion of DNA replication. Furthermore, DNA replication was likely to be even more prone to failure early in the evolution of cells, before very sophisticated replication machineries and repair pathways had been fully developed. Therefore, many scientists in the field now believe that

homologous recombination first evolved as a means to complete cellular DNA replication, and that all the other wonderful benefits of recombination came later.

Replication Fork Failure and Direct Restart Pathways

The above description of replication fork restart is incomplete, focusing only on the restart of forks that end up being broken. As might be expected, other pathways are able to directly restart stalled or blocked replication forks without the dangerous step of breaking the fork. Indeed, bacterial cells have multiple pathways for directly restarting forks. Although these pathways need not involve any recombination of the DNA molecules, some of the proteins that are involved in direct restart pathways are nonetheless recombination proteins that play roles in recombinational restart or other homologous recombination pathways.

One of the important unanswered questions is the fate of the various components of the replication machinery when forks are blocked or stall. It is clear that replication fork restart pathways require proteins that can load the replicative helicase, and so by inference, the replicative helicase seems to be lost when forks stop prematurely. We do not know which other components of the replication machinery are lost upon fork failure. Because the replicative helicase is thought to encircle the lagging-strand template, it is presumably lost whenever that strand is broken. In other cases (e.g., breakage of the leading strand and fork arrest without breakage), it remains to be determined how exactly the helicase is lost, and for that matter, whether the helicase is lost in only a subset of replication fork failures.

There are many possible reasons why a replication fork might stop prematurely. For example, a particular nucleotide might be temporarily limiting, a noncovalently bound protein might be encountered on the template duplex, or one of the key proteins of the replication machinery might become damaged or displaced from the replication fork. By sidestepping the question of how and why the replicative helicase and other proteins might be lost from such a fork, it is easy to see how direct restart pathways can solve the immediate problem and allow a completion of DNA replication.

However, the true complexities and benefits of replication fork restart pathways only become obvious when we consider other problems that a replication fork can encounter, particularly the many different forms of template DNA damage. The most obvious problem is when the replication machinery encounters a damaged base on the leading-strand template. In this case, one can easily see the advantage of disassembling the normal replication machinery – namely, that an appropriate DNA repair complex can be recruited to fix the template damage or, if that fails, a translesion DNA polymerase can be recruited to incorporate something opposite the damaged base (Figure 3; left). After the repair or translesion synthesis event, the normal replication machinery would need to be assembled to resume replication, hence the need for a direct restart pathway (or an RDR event if the fork has become broken). This description of the behavior of the replication fork at sites of template DNA damage is very superficial and incomplete,

Figure 3 Pathways for restarting replication forks. Replication forks may stall due to the absence of nucleotides or problems with the replication machinery, or may be blocked due to template damage or bound proteins ahead of the fork. If the fork was blocked by template damage, repair of the damage or translesion synthesis may precede direct fork restart. Some of these pathways involve a process called replication fork regression, where the two newly synthesized strands unwind from their parental templates and rewind with each other, creating a Holliday junction at the fork (this process is not shown in the figure). If the fork was simply stalled, direct fork restart can occur without repair. In either case, some or all of the replication proteins need to be re-assembled on the fork to re-initiate replication. In the pathway on the right, the stalled or blocked fork is broken, for example, by a recombination nuclease. Accurate restart of the fork by RDR (as in [Figure 2](#)) can lead to a normal cell without any genetic damage, but failure of this accurate pathway can lead to chromosomal rearrangements.

in part because there are many forms of damage and multiple pathways of repair. The more serious limitation at this time, however, is that the field is just beginning to investigate what promises to be a very rich area, this interface where DNA replication, repair and recombination all intersect at troubled replication forks.

Disturbances in Fork Processing Lead to Genome Instability and Cancer Predisposition

DNA breaks are inherently dangerous. A broken fragment of a chromosome that lacks the centromere may be lost during mitosis to generate a terminal chromosomal deletion (assuming that the centromere-containing fragment acquires a new telomere). A broken end might engage in a nonhomologous end-joining reaction, or if the end is located within a repeat region, might undergo homologous recombination with another copy of the repeat. In both cases, chromosomal deletions, inversions, and translocations can result.

With an understanding that DNA replication can lead to DNA breaks, it is therefore not surprising to find a strong association between disturbances in replication fork processing and genome instability. For example, studies in *S. cerevisiae* have shown that mutational inactivation of genes involved in the recombinational restart of replication forks (RDR) leads to genome instability. Apparently, when the normal pathway of restarting broken forks is disturbed, the broken DNA can result in chromosomal rearrangements ([Figure 3](#), right).

Cells from individuals who suffer from certain human cancer predisposition syndromes (Werner's, Bloom's, and Rothmund-Thomson syndrome) show increased genome instability. Genetic analysis has traced these defects to genes

that encode proteins that are suspected to be involved in replication fork integrity, recombinational restart of broken forks, and/or direct restart pathways. All three of these proteins belong to the RecQ family of DNA helicases (named after the founding member, bacterial RecQ). Several other human cancer predisposition syndromes have been shown to have defects in other recombination or DNA damage response genes. The precise role of these various proteins are under active investigation, and it is likely that at least in some cases, genome instability results from a defect in recombinational restart of broken forks or from a higher incidence of replication fork breakage. Increased fork breakage could potentially arise from a defect in a protein that is involved in direct restart pathways, or from any mutation that leads to more frequent fork arrest.

Current models for the generation of chromosomal rearrangements, including translocations, inversions, and gene amplifications, often invoke reactions including RDR and/or replication template strand switching. Particularly in the case of large gene amplifications, extensive DNA replication by an RDR-like mechanism seems very likely. Thus, RDR appears to play an important role in the genome instability that is critical in the generation and progression of cancer, and as described above, RDR is also important in telomere cancer biology.

In summary, the processes of DNA replication, recombination, and repair participate in an intricate choreography that is necessary for the accurate and complete replication of the genome, which in turn is important for genome stability and for the prevention of cancer in humans. RDR is a central aspect of this choreography, directly connecting homologous recombination to DNA replication and allowing the completion of replication when the replication fork becomes broken.

Glossary

Crossing-over A product of homologous recombination in which the arms of recombining molecules were reciprocally exchanged. In meiosis crossing-over constitutes 20–50% of the recombination products and occurs mostly between homologous chromosomes while in growing cells crossing-over represents only <1–10% of the products and recombination involves mainly sister chromatids.

Heteroduplex DNA Double-stranded DNA created during recombination from two complementary strands derived

from two DNA molecules. Strand-exchange proteins mediate heteroduplex DNA formation. The length of heteroduplex DNA ranges from few hundred bps to several kbs.

Holliday junction (HJ) Junction of four strands formed between two homologous DNA molecules in recombination. Double and single HJs were demonstrated as intermediates of meiotic recombination. HJs are cleaved by nucleases called resolvases.

Introduction

There are many sources of the DNA damage which is repaired by recombination. Single-strand gaps and breaks and double-strand breaks (DSBs) occur spontaneously during replication or are induced by radiation or radiomimetic chemicals. Some types of cells induce programmed DNA breaks to initiate meiotic recombination, V(D)J recombination, or class switching in the immune system. Additionally, some lower organisms such as baker's yeast induce single DSBs to initiate mating-type switching. In higher eukarya DNA recombination is essential for life, indicating that in each cell cycle there is spontaneous damage that needs to be repaired by DNA recombination. DNA recombination generates new combinations of alleles and is necessary for chromosome segregation during meiosis. Both the mechanisms and proteins involved in recombination are well conserved among all organisms.

Models of DNA Recombination

The DNA recombination events which are best understood at the molecular level are those initiated by DSBs. In mitotic cells DNA breaks can be induced by site-specific nucleases, such as HO endonuclease in yeast or I-SceI in mammals, and in meiotic cells by type II topoisomerase-related protein Spo11. Several models summarized in Figure 1 have been proposed to explain DSB-induced homologous recombination at the molecular level. All recombination events are initiated by formation of 3' single-stranded DNA (ssDNA) at DSB ends. This process is called 5'-strand resection. In the classic DSB repair model both ends invade the homologous donor sequence and prime new DNA synthesis to form a double Holliday junction intermediate (dHJ) (Figure 1(a), left). This dHJ is then resolved to form either a crossover or a noncrossover product. dHJs have been demonstrated to be the major intermediate of recombination in meiotic cells where crossover products are very frequent, while in mitotic cells both crossovers and dHJs are rare. A dHJ can be processed into

noncrossover products by type I topoisomerase (Figure 1(a), middle); however, crossover frequency in the absence of type I topoisomerases increases only slightly, suggesting that this is not a major noncrossover pathway. An alternative model of recombination called synthesis-dependent strand annealing (SDSA) has been proposed to account for low crossover in mitotic cells. In this model only one end invades its template to prime new DNA synthesis. The newly synthesized strand is then displaced from the template molecule and anneals to the second end of a DSB to form noncrossover product exclusively (Figure 1(a), right). In this case, both newly synthesized strands are inherited by the molecule that had been broken, as has been demonstrated for noncrossover recombination in mitotic cells in yeast. All these models of recombination explain repair of two-ended DSBs. However, it is likely that most of the breaks created spontaneously in cells during replication are single ended as shown in Figure 1(b). A single-ended DSB is formed when a replication fork runs into a DNA nick or a gap. These are repaired by break-induced replication (BIR). In BIR strand invasion is followed by DNA synthesis (both lagging and leading strands) to the next replication fork or to the end of the chromosome. This process requires most of the proteins involved in DNA synthesis during regular replication (Figure 1(b)). Finally, when a DSB is flanked by direct repeats as shown in Figure 1(c), upon resection the two repeats can anneal to each other and the sequence between the repeats and one repeat is lost. This type of repair is called single-strand annealing (SSA) and does not require a strand invasion step. Some rare recombination events or recombination in some organisms have distinct features not described by these models. For example, in fission yeast, single HJs (sHJs) are major intermediates of meiotic crossover recombination. Other examples include recombination pathways called microhomology-mediated end joining or microhomology-mediated BIR that are initiated by annealing of very short 2–15 nt sequences and lead to genome rearrangements frequently observed in cancer cells. These are rare but important pathways that are uncharacterized genetically and will not be discussed here.

Figure 1 Models of DNA recombination. (a) Models of two-ended DSB repair. In all models 5'-strands are resected and 3' ends invade a homologous molecule. In the dHJ model (left), both ends invade the homologous molecule and prime new DNA synthesis leading to the dHJ formation and resolution. Both crossovers and noncrossovers can be formed as outcomes of the resolvase-mediated cleavage indicated with black lines. In the dHJ dissolution model (middle), two HJs migrate toward each other forming a single catenane that is processed by type I topoisomerase to form only noncrossover product. In SDSA model (right), only one end primes new DNA synthesis and the newly synthesized DNA is dissociated from template and anneals to the second DSB end forming exclusively noncrossover product. DNA translocases, helicases, and nucleases working in each step of repair are indicated. Only yeast enzymes are shown; human homologs and functional homologs are shown in [Table 1](#). (b) Break-induced replication model for repair of one-ended DSBs. DNA helicases important specifically for this process are shown. (c) Single-strand annealing model for repair of a DNA break flanked by direct repeats. The Rad1 nuclease cleaves nonhomologous tails after annealing of direct repeats.

DNA Helicases

As shown in [Figure 1](#), recombination involves multiple strand-unwinding and DNA cleavage steps. DNA helicases and nucleases mediate these processes and are listed in [Table 1](#). DNA helicases are the enzymes that couple adenosine triphosphate (ATP) hydrolysis to unwinding of double-stranded DNA

(dsDNA). Helicases belong to a larger group of proteins called translocases that translocate on DNA. Many translocases cannot unwind duplex DNA but still play an important role in DNA repair. Translocases are classified into many groups based on their signature motifs. All of them contain motifs responsible for the binding and hydrolysis of ATP, and an arginine finger that presumably senses ATP binding and hydrolysis and

Table 1 Enzymes with translocase or nuclease activity in homologous recombination in yeast and human

Step in DNA recombination	Yeast	Human	Activity
5'-Strand resection	Mre11–Rad50–Xrs2	MRE11–RAD50–NBS1	Mre11 is 3'-exonuclease and ssDNA endonuclease
	Sae2	CtIP	Sae2 ssDNA nuclease

(?) indicates that there are conflicting observations.

signals for conformational changes essential for enzyme translocation. DNA helicases have either 3'–5' or 5'–3' polarity which means they translocate on the DNA strand they bind to in one or the other direction. Finally, DNA helicases may translocate on ssDNA or dsDNA. Additional domains within helicases confer binding specificity to different DNA structures or additional catalytic activities.

DNA Nucleases

DNA nucleases catalyze the cleavage of phosphodiester bonds between deoxyribose and the phosphate residue within the backbone of DNA strands. Nucleases that cleave near the ends of DNA molecules are called exonucleases while enzymes that cleave within a DNA strand and do not require a free DNA end for cleavage are called endonucleases. Some enzymes have both activities. As with helicases, exonucleases have either 3'–5' or 5'–3' polarity depending on the direction of DNA hydrolysis. Multiple nucleases play key roles in recombination, generating substrates and cleaving intermediates.

DSB End Resection: Helicases and Nucleases Generate ssDNA Substrate for DNA Recombination

The ends of DSBs need to be converted into ssDNA for recombination proteins to be loaded and for the DNA damage checkpoint to be activated. An average of 1–4 kb of ssDNA is generated on each side of a DSB during repair. It is then covered with strand-exchange protein Rad51, which is capable of genome-wide searching for homologous sequence. Checkpoint response proteins Mec1/Ddc2 in yeast and ATR/ATRIP in human bind ssDNA covered with ssDNA-binding proteins

RPA, and activate a kinase cascade that leads to cell-cycle arrest. In yeast Mre11–Rad50–Xrs2 (MRX complex, Mre11–Rad50–Nbs1 or MRN complex in human) together with Sae2 (CtIP in human) initiate the process of resection by generating short lengths of ssDNA and recruiting other nucleases that can generate longer ssDNA. Mre11 is an ssDNA endonuclease and 3'-exonuclease with polarity opposite to the polarity of resection. One possible mode by which Mre11 could generate short 3'-ssDNA is by cleavage of the 5'-strand of duplex DNA at some distance from the DSB ends, followed by its 3'-exonuclease-dependent degradation. Mre11 nuclease activity is essential for resection when the ends of DSBs are modified (e.g., by covalently bound proteins such as Spo11 or by adducts) in all eukarya that have been tested. In human and fission yeast, nuclease activity of Mre11 is required for resection even at clean (unmodified) DSB ends. By contrast, in budding yeast a nuclease mutant of *MRE11* has only a mild defect, while complete *MRE11* deletion has dramatic defect in resection. Mre11 nuclease is stimulated by Sae2, which also shows ssDNA nuclease activity *in vitro*. MRX, besides generating ssDNA itself, can also recruit nucleases Exo1 and Dna2 (in budding yeast) and Exo1 (in human) to DSB ends. This activity is Mre11 nuclease independent in yeast. Finally, MRX complex antagonizes excessive DSB end binding by Ku proteins that block resection. Exo1 is a 5'-exonuclease and has been shown to play a key role in generating longer ssDNA at DSBs during meiotic recombination and in processing stalled replication forks or ultraviolet (UV) light damage. In budding yeast mitotic cells, in addition to Exo1 there is also Dna2, a 5'-exonuclease involved in Okazaki fragment processing, which can resect DSB ends. While Exo1 can process 5'-strands by itself, Dna2 needs Sgs1 DNA helicase and RPA for resection. RPA stimulates 5'-strand cleavage by Dna2 and protects 3'-ends from Dna2 nuclease. Sgs1 forms a complex with topoisomerase Top3 and Rmi1 and

entire complex (called in yeast STR complex) but not Top3 catalytic activity is needed for normal resection. It is not yet clear why two resection pathways exist and whether Exo1 and Dna2 act entirely independently. Similarly to what is found in yeast, in humans Exo1 and the Sgs1 ortholog BLM are needed for resection while in frogs another Sgs1 ortholog called WRN and DNA2 nuclease are used. In human there are five Sgs1 orthologs, three of which (BLM, WRN, and RECQ5) play important roles in DNA recombination. Besides helicases and nucleases directly processing 5'-strands, at least two additional translocases that remodel chromatin stimulate resection. Yeast RSC complex recruits MRX complex to DSBs while INO80 likely displaces nucleosomes to stimulate resection (Table 1).

In prokaryotes several DNA helicase/nuclease complexes that resect DSBs have been described. In *Escherichia coli* a RecBCD heterotrimeric complex resects DSBs, where both RecB and RecD have helicase activity while RecC is also a nuclease. Both unwound strands are initially degraded until the complex reaches an 8-bp long sequence (5'-GCTGGTGG-3') called Chi, which is highly enriched in the *E. coli* genome. From the Chi sequence only the 5'-strand is degraded, exposing a long 3'-tail used to form RecA nucleofilament. RecB also directly helps to load the RecA protein at 3'-ssDNA. Similarly to eukaryotes, in *E. coli* RecQ helicase, an ortholog of Sgs1, together with RecJ, a 5'-3' ssDNA exonuclease, forms an ssDNA substrate for recombination. This presumably occurs at DNA damage where RecBCD has no access, such as DNA strand gaps. A functional homolog of RecBCD in *Bacillus subtilis* is AddAB, and in *Mycobacterium smegmatis* is AdnAB. AddAB is a complex of two nucleases and one helicase, while mycobacterial AdnA and AdnB both harbor helicase and nuclease domains. It remains to be determined if and how AddAB or AdnAB is controlled by sequences equivalent to Chi and whether like RecBCD they help to load RecA.

DNA Translocases in Strand Invasion, Branch Migration, and DNA Synthesis

When 3'-ssDNA is formed, Rad51 protein covers it, forming a nucleofilament, and mediates the strand-exchange process. Rad54, a member of the Snf2 family, can translocate on DNA (but has no helicase activity) and stimulate the strand-exchange process. It has been suggested that translocase activity could stimulate heteroduplex DNA formation by opening duplex donor DNA to facilitate interaction with the Rad51 nucleofilament. *In vitro* evidence suggests that Rad54 translocase plays several roles in recombination after heteroduplex DNA is formed. First, Rad54 stimulates Rad51 pairing activity and therefore extends heteroduplex DNA. Second, in yeast Rad54 and its homolog Rdh54 displace Rad51 from heteroduplex DNA and presumably facilitate DNA synthesis primed by invading 3'-ends. Finally, Rad54 promotes 3- and 4-strand branch migration. This activity can extend or shorten heteroduplex DNA at the D-loop stage or after full HJs are formed (Figure 1(a)). DNA synthesis by Pol δ in yeast in the context of D-loop is stimulated by a 5'-3' DNA helicase called Pif1, while extensive DNA synthesis during BIR requires the replicative helicase Mcm2-7.

Removal of Terminal Nonhomology by Yeast Rad1/ (Rad10) Nuclease

When the ends of invading strand are nonhomologous, DNA polymerase cannot use the ends for extension until the terminal nonhomology is removed. In yeast very short terminal nonhomologous sequences (≤ 10 nt) can be removed by the proofreading 3'-5' exonuclease activity of polymerase δ . Longer nonhomologous tails require a structure-specific 3'-endonuclease called Rad1 and its associated protein Rad10 (XPF-ERCC1 in human), which also plays a key role in nucleotide excision repair (NER). Nonhomologous tails are formed during the SSA recombination pathway upon resection and annealing of two repeats (Figure 1(c)). Besides Rad1 nuclease, two mismatch repair proteins, Msh2 and Msh3, stimulate removal of nonhomologous tails presumably by stabilizing invading 3'-strands carrying terminal nonhomology. Saw1 is another accessory protein which has been shown to recruit Rad1/Rad10 specifically for nonhomologous tail removal, but plays no role in NER. In addition, Slx4, but not its endonuclease partner Slx1 (discussed below), is essential for Rad1-Rad10 cleavage. Slx4 needs to be phosphorylated by DNA damage checkpoint proteins (Mec1/Tel1) to participate in nonhomologous tail removal. However, the specific function of Slx4 in Rad1 cleavage is not known. The same Rad1/Rad10 nuclease is used for removal of long nonhomologous sequences that form large loops in heteroduplex DNA.

Multiple DNA Helicases and Nucleases Involved in Resolution of Recombination Intermediates

Once 3'-ends invade the homologous molecule, they prime new DNA synthesis. Based on genetic and biochemical evidence, it is assumed that the majority of noncrossover products in mitotic and even meiotic cells result from unwinding of newly synthesized 3'-strands (D-loop dissociation) as described in SDSA model of recombination (Figure 1(a), right). Several DNA helicases have been shown to catalyze D-loop dissociation. When both 3'-strands invade donor molecule and initiate synthesis, dHJs are formed that can be resolved into crossover products. In this case, nucleases called resolvases, which cleave 4-stranded junctions, are required to complete repair. Resolvases have been well characterized in prokaryotes and were recently identified in eukaryotes as well.

Enzymes Disrupting D-Loops

Several DNA helicases have been proposed to promote the noncrossover pathway via D-loop unwinding. In budding yeast, mutants deficient in Srs2 or Mph1 helicases show increased crossovers; additionally, double mutants have a more than additive effect, suggesting that Srs2 and Mph1 play at least partially overlapping roles in preventing crossover formation. Fission yeast homologs of these helicases called Srs2 and Fml1 also limit crossover recombination in mitotic cells. Consistent with this, purified Mph1 and Fml1 helicases unwind Rad51-made D-loops *in vitro*. In addition, human FANCM, BLM, WRN, and RTEL-1 have been shown to

dissociate D-loops *in vitro*. As mentioned above, yeast Rad54 can also promote 3-stranded branch migration such as those at D-loops, raising the possibility that it unwinds D-loops as well. BLM-, RTEL-1-, and FANCM-deficient cells show increased crossover frequency, while the role of Rad54 in crossover regulation has not been established in cells because it is an essential and multifunctional protein in recombination. Disruption of D-loops before 3'-invading strands prime new DNA synthesis would simply inhibit recombination, and, as discussed below, some of these helicases prevent recombination under certain circumstances. How these helicases are regulated either to stimulate SDSA or to inhibit recombination, or in other words to unwind D-loops before or after the 3'-invading strand initiates new DNA synthesis, is not known but may be related to the stability of invading ends and/or length of heteroduplex DNA.

Resolution of HJs

When both 3'-ends invade and prime new DNA synthesis, dHJs are formed that can be resolved to either crossover or noncrossover product by resolvases. HJ resolvases are nucleases that nick two strands symmetrically at or near to the junction point. The nicked molecules are then repaired by DNA ligation, resulting in either crossover or noncrossover products (Figure 1(a), left). In prokaryotes, RuvC resolves HJ by symmetrical cleavage. In eukaryotes that do not have orthologs of RuvC (except mitochondrial Cce1), several enzymes were identified which resolve HJs. The first complex, called MUS81-EME1 in human and Mus81-Mms4 in budding yeast, is related to Rad1/XPF. It preferentially cleaves nicked HJs while intact HJs are poor substrates and their cleavage is not symmetrical. The second nuclease capable of cleaving intact HJs, and does it symmetrically, is Yen1 in budding yeast and its ortholog GEN1 in human. These enzymes belong to the Rad2/XPG nuclease family that includes XPG nuclease, Exo1, and Okazaki fragment-processing enzyme Fen1. The third eukaryotic enzyme able to cleave HJs, SLX1, was identified in humans. Human SLX1 forms a heterodimer with SLX4 and cleaves HJs symmetrically, while their fungal orthologs Slx1-Slx4 cleave HJs very poorly and asymmetrically. Finally, in *Drosophila melanogaster* MEI9, an ortholog of XPF that also forms a complex with an SLX4 ortholog called MUS312 in flies plays a crucial role in meiotic crossing over presumably by resolving HJs. Similarly, in *Caenorhabditis elegans* SLX4 and XPF orthologs, but not MUS81 or GEN1 orthologs, play a crucial role in meiotic recombination and the crossover pathway, while the function of SLX1 orthologs has not yet been established. As described above, SLX4 serves as a platform interacting with multiple endonucleases, possibly coordinating cleavage of different structures arising during repair.

While biochemical properties of the eukaryotic resolvases have been described carefully, their contribution to resolution of HJs *in vivo* remains unclear, as most model organisms tested so far seem to have distinct major proteins resolving HJs. *D. melanogaster* and *C. elegans* use mostly XPF nuclease in crossover recombination. In fission yeast, which lack a Yen1/GEN1 homolog, elimination of mus81 dramatically decreases crossover outcomes while noncrossovers remain unaffected. By contrast, in budding yeast elimination of Mus81 or Yen1

has little to no effect on crossovers in both meiotic and mitotic recombination, while mus81 yen1 double mutants show a significant decrease in crossovers and severe sensitivity to DNA damage. In higher eukaryotes MUS81/EME1 seems to play an even less significant role, because mutants lacking these enzymes show no defect in the meiotic cycle or sensitivity to ionizing radiation. However, again double mutants lacking both MUS81 and GEN1 are very sensitive to DNA damage. Taken together, it seems that Mus81 and Yen1 in yeast and MUS81 and GEN1 in human play overlapping roles in HJ resolution. It remains to be determined what the function of SLX1 and XPF in generating crossovers is, particularly in the absence of Mus81 and Yen1/Gen1 in yeast and human. More research is required to understand specific functions of each resolvase in mitotic and meiotic recombination.

Dissolution of HJs by Helicase/Topoisomerase Complex

In BLM mutants in human and *sgs1Δ* in yeast, the number of crossovers, particularly spontaneous sister chromatid exchanges, is increased. Similarly to resection mediated by these helicases, crossover suppression requires type IA topoisomerase, Top3, and Rmi1 components of the STR complex. What distinguishes the STR complex function in resection from its function in processing of dHJs is the catalytic activity of Top3. Strand passage activity is not required for resection; however, it is essential for crossover suppression. A mechanism proposed for this anticrossover activity suggests that BLM/Sgs1 helicases branch-migrate two Holiday junctions toward each other, thus creating a single catenane that is further resolved by type I topoisomerase into two separate DNA molecules to create a noncrossover product (Figure 1(a), middle). This activity is called dHJ dissolution and has been demonstrated in *in vitro* studies. As discussed above, BLM also dissociates D-loops, suggesting that it may suppress crossovers both by dissolution of dHJs and by unwinding D-loops.

DNA Helicases Inhibiting DNA Recombination

DNA recombination is an essential pathway of DSB repair. However, its use must be tightly regulated to limit recombination between very short repeats or excessive involvement during replication or other DNA transactions with ssDNA intermediates. Several DNA helicases prevent undesired DNA recombination and they act at different stages of recombination. Interestingly, these are the same helicases that, under different circumstances, promote recombination. In yeast at least three DNA helicases, Srs2, Sgs1, and Mph1, have both pro- and anti-recombinogenic functions. In mutants deficient in Srs2 and Sgs1, and particularly both Sgs1 and Mph1, spontaneous recombination is dramatically increased. Sgs1 might be particularly adept at inhibiting recombination between short homologous or partially homologous (homeologous) sequences, presumably by unwinding unstable heteroduplex DNA. Also, Sgs1 may suppress spontaneous DNA damage from initiating recombination by stabilizing stressed replication forks. On the molecular level, DNA helicases suppress homologous recombination in at least two different ways. First, they strip strand-exchange protein from ssDNA, and second they

unwind the initial intermediates of DNA recombination, the D-loops. DNA helicases able to strip Rad51 from ssDNA have been identified in bacteria, yeast, and higher eukaryotes. Yeast Srs2 and its *E. coli* homolog UvrD efficiently disrupt the pre-synaptic Rad51 (*EcRecA*) nucleofilaments, and thus inhibit the strand-exchange processes. Translocase (but not helicase) activity of Srs2, as well as its Rad51-interacting domain, appear to be essential for this process. One of the major functions of Srs2 as an anti-recombinase is to inhibit recombination in the context of replication forks to favor Rad6/Rad18-dependent postreplication repair. When recombination is the only means of repair, such as at DSB ends, Srs2 activity is antagonized by proteins called Rad52 and Rad55/Rad57 that mediate Rad51 loading. How cells regulate the antagonizing activities of Srs2 and Rad51 assembly mediators at different DNA substrates is not known. In mammals, RECQ5 helicase has been shown to possess similar activity to Srs2. Mouse mutants deficient in RECQ5 consistently show increased recombination rates, longer lasting Rad51 nuclear damage foci, genomic instability, and increased cancer predisposition. Additionally, BLM helicase can strip Rad51 from ssDNA *in vitro*; however, unlike RECQ5, BLM also inhibits recombination by unwinding Rad51-generated D-loops. Given multiple activities of mammalian BLM and yeast Sgs1, it is likely that a combination of several activities is important to prevent unscheduled recombination and genome rearrangements. Besides BLM, metazoan RTEL-1 and yeast Mph1 also unwind Rad51-made D-loops, an activity likely contributing to their anti-recombinase activities. Finally, Rad51 and its homolog expressed in meiotic cycle, Dmc1, can bind double-stranded DNA. However, these complexes do not produce recombination but may stimulate genomic instability. Several DNA translocases including Rad54, Rdh54, and Ulp1 disassemble such dsDNA-bound Rad51.

Nucleases in NHEJ

In NHEJ, two ends of a DSB are joined to restore the original sequence, and in most cases nuclease activity is not required for such repair. However, when the DNA ends are modified by adducts produced by ionizing radiation, or when hairpins or overhangs are created at DSB ends such as during V(D)J recombination, nuclease becomes essential for processing the DSB ends to allow subsequent ligation. Artemis has been identified in vertebrates as a major nuclease processing alternative DSB ends. Consequently, Artemis-deficient cells are radiosensitive and not capable of V(D)J recombination. Artemis belongs to the SNM1 family of nucleases that includes Pso2 in yeast and three nucleases in vertebrates, SNM1A (ortholog of yeast Pso2), SNM1B (known also as Apollo), and SNM1C (Artemis).

Artemis alone has a 5′–3′ exonuclease activity and an ssDNA endonuclease activity; when phosphorylated by and bound to DNA PKcs, it also possesses a dsDNA endonuclease activity and targets the junction of ssDNA and dsDNA. DNA PKcs is an essential protein kinase for NHEJ in higher eukarya, and is activated by binding to DNA. Artemis/DNA PKcs can act on a variety of substrates, including hairpins, 3′ and 5′ overhangs, and loops, and it generates either blunt ends or short 3′-overhanging ends. Processing of such structures by Artemis is crucial for repair by NHEJ, and some reports suggest that it may play a role in a fraction of homologous recombination.

Conclusions

DNA helicases and nucleases are key enzymes in DNA recombination. The molecular function of many of them has been identified, and their biochemical activities described. Individual helicases and nucleases play multiple roles during recombination, and the same step of recombination can be catalyzed by different helicases or nucleases. Also, helicases often have both pro- and anti-recombinogenic activities. Therefore, the next challenge is to identify mechanisms for the control of DNA helicases and nucleases by posttranslational modifications or by protein–protein interactions.

Glossary

DNA joint molecule Two formerly distinct DNA molecules that are joined by base-pairing interactions and/or the DNA-strand transferase filament. Unlike heteroduplex DNA, this term includes synapsed DNA structures whose strands have not yet intertwined (paranemes) or where the heteroduplex DNA has been repaired by mismatch repair.

DNA translocase A motor protein whose adenosine triphosphatase cycle is coupled to movement on DNA.

Heteroduplex DNA The duplex DNA product of DNA-strand exchange, where the two component single strands were originally part of two separate DNA molecules.

Paralog A type of homolog where genes are related by duplication within an organism's genome that led to their specialization of functions.

Homologous recombination (HR) is highly reliant on the DNA-strand transferases that catalyze the key reactions of homology search and DNA-strand exchange. The prototype for this class of enzymes is RecA protein from *Escherichia coli*. Other members include UvsX from T4 bacteriophage, RadA from Archaea, Rad51 from eukaryotes, and the meiosis-specific Dmc1 protein, found in most, but not all, eukaryotes. Defects in DNA-strand transferases lead to a severe reduction in HR associated with DNA damage sensitivity as well as impaired replication and meiotic chromosome metabolism.

Homology Search and DNA-Strand Invasion by DNA-Strand Transferases

DNA-strand transferases catalyze homologous pairing between single-stranded DNA (ssDNA) and double-stranded DNA (dsDNA, or duplex DNA), followed by the exchange of one strand of the dsDNA with the incoming ssDNA. The product of the DNA-strand exchange process is heteroduplex DNA, in which two single strands of DNA that were formerly from distinct DNA molecules form duplex DNA, displacing the original complementary duplex strand in the region where strand exchange has occurred. This DNA-strand invasion reaction is fundamentally different from DNA-strand annealing, where two ssDNA regions come together to form duplex DNA, because it requires DNA-strand displacement and the original base pairs to be broken. The DNA substrates required for recombination are typically the 3'-overhanging ssDNA from a processed DNA double-strand break (DSB) or ssDNA gaps formed during replication fork stalling (Figure 1) or other processes. The fundamental goal of a recombination reaction is a template switch to provide a 3'-OH primer a suitable template for DNA synthesis. This synthesis allows the cell to reference and recover sequence from an intact copy of a genetic locus when the other has been damaged.

DNA-Strand Transferase Filament Formation

The catalytic form of DNA-strand transferases is a specialized, right-handed helical filament that forms on ssDNA with

approximately six monomers per turn. The first challenge of HR is to assemble these nucleoprotein filaments so the homology search can begin. *In vivo*, the ssDNA substrate for filament formation is coated with ssDNA-binding protein (bacterial SSB, phage T4 Gp32, or eukaryotic RPA) as soon as it is generated. Although the binding of successive DNA-strand transferase monomers to filament ends is cooperative, competition for ssDNA binding with the ssDNA-binding proteins limits the initiation of filament formation, a process termed nucleation. In the cell, nucleation of the first monomers and the replacement of ssDNA-binding protein by growing DNA-strand transferase filaments are assisted by additional proteins, termed recombination mediators (see below). The eukaryotic DNA-strand transferases Rad51 and Dmc1 have added reliance on accessory proteins, as they lack the strong binding preference for ssDNA over dsDNA exhibited by RecA and UvsX. Consequently, *in vivo*, Rad51 or Dmc1 require assistance to be targeted to ssDNA, and filaments that have formed on dsDNA must be dissociated. The evolutionary constraints that led to these differences between DNA-strand transferases from eubacteria and eukaryotes are not understood yet, but likely are adaptations to the more complex genomes and regulatory requirements of eukaryotic organisms. Generation of ssDNA, nucleation, and extension of DNA strand transferase filaments are required to form the presynaptic nucleoprotein structure that is active for recombination, the generation of which is the primary challenge of the early steps of HR. This process is generally termed presynapsis, and the presynaptic filament is necessary for all subsequent steps of HR.

Homology Search and Paranemic Joint Formation

The presynaptic filament on ssDNA searches for homology in the genome. The homology search process is poorly understood, but a key feature is the stretching of the bound DNA in the confines of the filament by 150% relative to B-form DNA. Presumably, homology search involves many rounds of association/dissociation between the ssDNA filament and duplex DNA to sample homology by Watson–Crick base pairing. Finally, a region of

Figure 1 Involvement of DNA-strand transferases in DSB and gap repair by homologous recombination. (a) Double-strand break repair by synthesis-dependent strand annealing (SDSA). After DSB formation, nucleolytic DNA end-processing creates 3'-ended ssDNA that becomes the substrate for DNA strand transferase filament formation (spheres; not to scale or form). Homology search leads to the formation of a paranemic joint, which transitions to a plectonemic joint (D-loop) after strand intertwining. Upon dissociation of the DNA strand transferase from the heteroduplex product, the invading strand 3' end is extended by DNA polymerase. SDSA is one pathway of DSB repair, and alternative pathways differ only in the steps after DNA synthesis (see suggested readings). In SDSA, the extended invading ssDNA retracts from the D-loop and anneals to the complementary strand of the other DSB end. Synthesis to fill in the remaining gaps and sealing of the nicks by ligation results in a fully restored chromosome. (b) Gap repair by homologous recombination. Recombination from a gap on the lagging strand can displace the newly synthesized leading strand for use as a template for DNA synthesis past a blocking DNA lesion (black box). Notice that the initial joint molecule that forms is an obligatory paraneme because there is no free DNA end to allow strand intertwining. DNA within the strand transferase-ssDNA filament is homologically aligned with duplex DNA, marking the beginning of the synapsis stage of HR. The initial synaptic complex is termed a paranemic (from Greek, literally 'beside thread') joint DNA

molecule, and it is stable only in the continued presence of the DNA-strand transferase protein. At this stage, there is no net intertwining of the incoming ssDNA with its complement that has been found in the dsDNA.

Plectonemic Joint Formation

After homology search and homologous alignment in the paranemic joint, the invading strand must intertwine with its complement in the duplex DNA, thereby displacing the original complementary strand in the duplex from base-pairing interactions. The resulting intermediate is known as a displacement loop (D-loop). The 3'-end must intertwine to generate a suitable primer/template junction that can be extended by a DNA polymerase. Once intertwined, the existence of the homologously paired joint DNA molecule is no longer dependent on the continued presence of the DNA-strand transferase filament, as the newly formed heteroduplex DNA stabilizes the joint DNA molecule. Such intermediates where strands from two homologous DNA molecules have intertwined are termed plectonemic (literally, 'knotted threads') joint DNA molecules. They have been experimentally shown to form after paranemic joints, their direct precursors.

The transition from a paranemic to plectonemic joint requires the presence of a free DNA end in either the incoming ssDNA or duplex DNA donor to allow the free rotation required for DNA-strand intertwining. Therefore, the initial joint molecule that forms from an ssDNA gap, where there is no free DNA end, is an obligatory paraneme. Conversely, the ssDNA substrate for DSB repair has a free 3'-end, such that paranemes are likely kinetic intermediates on the way to becoming plectonemic joint molecules.

Filament Dissociation

The continued presence of the DNA-strand transferase on the region of intertwined homology within the plectonemic joint (heteroduplex DNA) can actually inhibit further steps in HR, because it obstructs the 3'-ssDNA end from access by a DNA polymerase to initiate DNA repair synthesis. Therefore, the DNA-strand transferase must either self-dissociate or be removed by an external factor. Both types of turnover have been observed.

DNA-strand transferases are DNA-dependent ATPases, and the ATPase cycle modulates the affinity of the DNA-strand transferase for DNA. The adenosine triphosphate (ATP)-bound form has the highest affinity for DNA, and for RecA the adenosine diphosphate (ADP)-bound form has the lowest, even lower than the nucleotide-free form. ATP hydrolysis is thought to occur throughout the filament, but because of cooperative interactions between monomers within, dissociation occurs primarily from ADP-bound monomers at the ends. For DNA-strand transferases with higher ATPase activities such as RecA ($\sim 30 \text{ min}^{-1}$) and UvsX ($\sim 200 \text{ min}^{-1}$), this appears to be sufficient for autonomous turnover from heteroduplex DNA. However, eukaryotic Rad51 proteins have a relatively low ATPase activity (< 1 ATP hydrolyzed per minute), and their ADP-bound form has considerably higher affinity to DNA than RecA leading to very inefficient turnover from dsDNA. These biochemical differences between the RecA and Rad51 proteins explain the necessity for external turnover factors that dissociate Rad51 from dsDNA.

Restoration of Information and Chromosome Resolution

The fundamental purpose of homology search and DNA-strand invasion by the DNA-strand transferase filament is to position the 3'-end of a DSB onto a suitable template for repair DNA synthesis that ultimately leads to the restoration of chromosomal integrity (Figure 1(a)). Similarly in gap repair, DNA-strand exchange leads to a template switch that provides an intact template for a 3'-end that could not otherwise be extended due to a damaged template (Figure 1(b)).

Structure and Properties of DNA-Strand Transferase Filaments

General Properties of DNA-Strand Transferases

DNA-strand transferases share homology in their central core, called the RecA domain, that shows a considerable degree of

Figure 2 Schematic alignment of DNA-strand transferases from Eubacteria, Eukaryotes, Archaea, and T4 virus. Black boxes indicate the location of the conserved Walker A and B ATP-binding motifs within the core domain. Numbers denote amino acid residues. Sequence representations are approximately to scale. *Ec*, *Escherichia coli*; *Hs*, *Homo sapiens*; *Sc*, *Saccharomyces cerevisiae*; T4, T4 bacteriophage; *Pf*, *Pyrococcus furiosus*. Copyright (2001) National Academy of Sciences, U.S.A.

sequence conservation between species and contains the ATPase active site as well as residues involved in DNA binding (Figure 2). Amino and carboxy-terminal domains are also present which are more variable between species. RecA has an N-terminal domain (aa 1–33), followed by the core domain (aa 34–240), and a C-terminal domain which contains a DNA-binding site (aa 241–352). In comparison, Rad51 proteins have an extended N-terminal region containing a DNA-binding site and lack the C-terminal domain found in RecA.

ATP Hydrolysis within the Filament

ATP hydrolysis is coupled to changes in the conformation of the DNA-strand transferase filament. X-ray crystallography and electron microscopy studies have observed RecA and Rad51

filament structures with distinctly different pitches, correlating to the identity of the bound nucleotide cofactor (Figure 3). An ATP-bound-like state exists in an extended filament conformation with a pitch of about 94 Å/turn, stretching the DNA within to about 150% relative to B-form DNA. The ADP-bound state, however, is in comparison more compressed, with a pitch of 65–85 Å/turn and does not appreciably extend DNA. The extended filament, trapped by the use of slowly hydrolyzable ATP analogs, has been correlated with activity using *in vitro* assays such as the D-loop assay which measures plectonemic joint formation between an ssDNA and a homology-containing supercoiled plasmid (Figure 4(b)). Consequently, and because conditions favoring formation of the compressed filaments do not lead to DNA-strand exchange, the extended filament has been described as the ‘active’ form of DNA-strand transferase

Figure 3 Structure of DNA-strand transferase filaments. (a) EM reconstructions of human RAD51 filaments in the extended (left, 99 Å pitch) and compressed (right, 76 Å pitch) conformations. (b) EM reconstructions of extended filament conformations of three DNA-strand transferases, left to right: human RAD51, *S. cerevisiae* Rad51, and RecA. (c) RecA crystal structure snapshot showing a nucleotide triplet bound by the primary monomer (RecA⁰). The triplet also makes contacts with RecA monomers 5' and 3' of the primary monomer. Notice the insertion of loop 2 (L2) residues between triplet base stacks. (d) RecA extended filament ssDNA electron density, with bases in triplets numbered 1–3. Notice the stretched and negatively twisted intertriplet base step between nucleotide triplets. (a, b) Modified from Yu X, Jacobs SA, West SC, et al. (2001) Domain structure and dynamics in the helical filaments formed by RecA and Rad51 on DNA. *Proceedings of the National Academy of Sciences of the United States of America* 98: 8419–8424. (c, d) Modified from Chen Z, Yang H, and Pavletich NP (2008) Mechanism of homologous recombination from the RecA-ssDNA/dsDNA structures. *Nature* 453: 489–484.

filament, and the compressed form 'inactive'. However, single DNA molecule studies with Rad51 protein have shown that ATP hydrolysis, while leading to partial contraction of the filament, does not necessarily lead to DNA-strand transferase dissociation. The same filament is able to rebind ATP and again adopt a fully extended conformation. Therefore, it appears that ATP hydrolysis, ADP dissociation, and the rebinding of ATP lead to dynamic changes in the pitch of the DNA-strand transferase filament. It is not known if this plays a part in the DNA-strand transferase reaction, but DNA extension appears crucial for the homology search step.

Structure of the RecA-ssDNA Extended Filament

The X-ray crystal structure of RecA bound to ssDNA in the extended filament conformation (pitch of 94 Å/turn) provides key insights into the cooperative interactions within the filament between ATP, DNA, and adjacent monomers of RecA (Figure 3). Hydrogen bond networks link bound ssDNA to the ATPase active site, such that without DNA binding there would be no ordering of critical residues for ATPase activity. The active site is located at the RecA–RecA interface, with the ADP- AlF_4 (ATP transition state analog) completely buried between monomers, in contrast to the compressed filament structure where the nucleotide is partly solvent exposed. In the extended filament, the core domains undergo a rotation that creates a new interaction surface between monomers. Now, critical lysine residues from the 3'-adjacent RecA monomer, K248 and K250, are positioned to make charge-stabilized H-bonds to the ATP γ -phosphate and E96, another important residue thought to activate a water molecule for nucleophilic attack on the γ -phosphate. ATP hydrolysis destabilizes the inter-monomer interface, because it eliminates these favorable interactions and introduces a net charge in a buried environment.

Perhaps the most surprising information from the RecA-ssDNA crystal structure is the way in which the DNA is extended, which has profound implications for the homology search process. The DNA inside the filament is stretched to

5.1 Å per base (compared to 3.4 Å per base pair in free dsDNA), and untwisted to 18.5 bases per turn (compared to 10.5 base pairs per turn in free dsDNA). However, this stretching of DNA is not accomplished uniformly along the length of the DNA. Instead, each RecA monomer binds three nucleotides of DNA and holds them with close to B-DNA rise values (3.8–4.2 Å per nucleotide; B-DNA is 3.4 Å). Most of the 1.5-fold extension relative to B-DNA is accomplished by the stretched (7.1–7.8 Å rise) and negatively twisted (-42°) base steps between these nucleotide triplets, from the 3'-most base of one triplet to the first base of the next triplet. This stretching is accomplished by the insertion of hydrophobic residues in the L2 loop region into the base stacks between nucleotide triplets.

Implications of Filament Structure for the Homology Search

The structure of the RecA-ssDNA filament suggests that for greater than three nucleotides in dsDNA to be consecutively base-paired with nucleotides in the extended filament, the dsDNA too must extend (untwist) in the same pattern of triplet stacked bases intervened by unstacked and stretched intertriplet gaps. To accomplish this, RecA has a secondary DNA-binding site that is thought to interact with one strand of duplex DNA to destabilize the helix and allow bases to be sampled for complementarity. Because net unstacking of base pairs is necessary to pair consecutive triplets, this may favor correct homologous alignment by requiring that the next triplet of dsDNA paired be fully homologous in order to energetically favor base unstacking. Furthermore, triplet isolation limits cooperative base stacking interactions with nonhomologous bases as the heteroduplex region extends, requiring the selectivity be based more on Watson–Crick hydrogen bond interactions.

Although there are now crystal structures of RecA available bound to both ssDNA and dsDNA, one intermediate remains elusive – the three-stranded, synapsed paranemic joint. It is not known how the DNA strands are arranged in the joint molecule to allow homologous pairing without net intertwining of DNA strands. It is thought that the bases in the target duplex are

flipped out for sampling, that is, they temporarily and reversibly break their Watson–Crick hydrogen bonds with the other duplex strand, assume a new orientation, and sample base pairing with nucleotides inside of the DNA-strand transferase filament. The extension of bound DNA by the presynaptic filament reduces stacking interactions to facilitate base flipping, and the structure suggests that the basic sampling unit for base flipping and homology search is the nucleotide triplet.

Recombination Mediators and Other Factors

Nucleation is the rate-limiting step for Rad51 filament formation and, consistent with other filament-forming proteins such as actin and tubulin, nucleation is a key regulatory target involving recombination mediators and other protein factors. Some of these proteins may also be involved in maintaining filament stability to increase the steady-state level of active DNA-strand transferase filaments.

Mediators for Presynaptic Filament Formation

DNA-strand transferases are impeded from nucleating filaments when ssDNA-binding proteins saturate ssDNA. Recombination mediators were defined biochemically as proteins that allow filament formation of DNA-strand transferases on ssDNA coated by the cognate ssDNA-binding protein. The prototypical recombination mediator is UvsY protein from bacteriophage T4, which overcomes the block to ssDNA binding imposed by Gp32 SSB protein to allow UvsX filament formation. RecFOR provides this function in *E. coli* for RecA protein. In eukaryotes, the situation is more complex. *S. cerevisiae* Rad52, the ortholog of UvsY and RecO proteins, mediates Rad51 filament formation *in vitro*, but human protein does not. Instead, in eukaryotes containing the BRCA2 protein, the mediator function is occupied by this protein, which was identified as a central tumor suppressor protein for breast and ovarian cancers.

Rad54, a Specialized DNA Translocase Working with Rad51

Rad54 is a member of the Snf-2 family, a class of proteins that remodel specific protein–dsDNA complexes, such as nucleosomes or the complex between TATA-binding protein and the TATA box. Rad54 and its paralogs Rdh54 in *Saccharomyces cerevisiae* or RAD54B in human exhibit robust dsDNA-specific ATPase activity, and translocate on DNA (in the case of the yeast enzyme at 300 base pairs per second). Rad54 and its paralogs interact with Rad51 or Dmc1 and stimulate recombination in a species-specific manner. *In vitro*, Rad54 exerts multiple functions, including stabilization of the Rad51 filament on ssDNA (presynapsis), enhancing D-loop formation or DNA-strand exchange (synapsis), as well as branch migration and dissociation of the DNA-strand transferase filament on dsDNA (postsynapsis). Dissociation of Rad51 or Dmc1 is required to allow access by DNA polymerase to the invading 3'-end. In addition, Rad54 and Rdh54 are able to move nucleosomes on dsDNA. While Rad54 is critical for recombination *in vivo*, it is unclear which specific biochemical activity(ies) is most required for its *in vivo* function(s).

Other Eukaryotic DNA-Strand Transferase-Enhancing Proteins

In eukaryotes, new classes of proteins have been discovered that functionally and structurally interact with Rad51 or Dmc1. These include the Rad51 paralogs, Rad55–Rad57 as well as Shu1 and Psy3, in *S. cerevisiae*. In humans, RAD51 paralogs include five members – RAD51B, RAD51C, RAD51D, XRCC2, and XRCC3 – forming two main complexes (B–C–D–X2 and C–X3). In addition, the human breast and ovarian tumor suppressor BRCA2 bind multiple molecules of RAD51 and other proteins, including PALB2 and DSS1, that are expected to play a role in recombination. While it is known that these factors interact with Rad51, directly or indirectly, their exact function remains to be determined. The multitude of factors that interact with Rad51 and that are genetically implicated in recombination suggests complex regulation of the assembly, stability, and function of the Rad51–ssDNA filament.

Anti-Recombinases Target the Rad51-ssDNA Filaments for Disassembly

While recombination is an active DNA repair mechanism, inappropriate recombination can interfere with other cellular processes such as DNA replication or lead to toxic intermediates. In eukaryotes, anti-recombinases have been identified genetically that enforce negative control on HR. The Srs2 DNA helicase was identified genetically in *S. cerevisiae* as an anti-recombinase. Translocation of Srs2 dissociates Rad51 from ssDNA leading to disassembly of presynaptic filaments. Srs2 is the archetype for such an anti-recombinase activity, and other eukaryotic proteins, including FANCI, FBH1, RECQ5, and BLM, were shown to dissociate Rad51 from ssDNA. In summary, the DNA-strand transferase presynaptic filament appears to be controlled in a meta-stable balance between processes that control its assembly and disassembly.

In Vitro Assays for DNA-Strand Transferase Activity

Functional *in vitro* assays for DNA-strand transferases have generated a detailed mechanistic understanding of their function and have provided test systems for the identification and characterization of recombination mediators and other accessory proteins (Figure 4).

Filter-Binding Assay for Detection of Paranemic Joint Molecules

The formation of the initial product of synapsis, the paranemic joint, is difficult to study because of its metastable nature, existing only in the presence of the DNA-strand transferase filament. The D-loop and DNA-strand exchange assays (discussed below), while being invaluable for the study of DNA-strand transferase reactions, are limited in that they can only detect stable plectonemic joint molecules where the DNA strands have already intertwined. A filter-binding assay, developed for RecA protein, can detect paranemic joints because it does not require deproteinization of reactions (Figure 4(a)). RecA filaments are first formed on

circular ssDNA and then are paired with homologous supercoiled plasmid DNA that has been labeled with tritium. Lack of a free DNA end in the DNA substrates ensures that all joint molecules formed are paranemic, since they cannot intertwine. To detect the presence of joint molecules, the reactions are diluted in a high-salt buffer and passed through nitrocellulose filters. The filter selectively binds ssDNA and any tritiated plasmid that is complexed to it by RecA in paranemic joint DNA molecules. The level of joint molecules is determined by scintillation counting of the washed filters. A major limitation to this assay is that protein binding to dsDNA causes the plasmid to bind the filter regardless of it being complexed in a joint molecule with ssDNA or not. Therefore, the assay is not suitable for DNA-strand transferases that lack an ssDNA-binding preference, such as the Rad51 or Dmc1 proteins.

The D-Loop Assay

The D-loop assay (Figure 4(b)) is a versatile and sensitive way to detect DNA-strand transferase activity *in vitro*. The ssDNA substrate is commonly a synthetic oligonucleotide that has been 5'-end-labeled with ^{32}P , while the dsDNA homology donor is a small (~ 3 kb), negatively supercoiled plasmid. DNA-strand transferase filaments are first formed on the oligonucleotide. The supercoiled DNA is then added and D-loops form when the oligonucleotide is incorporated into the plasmid as a plectoneme. After deproteinization, the reactions are analyzed by agarose gel electrophoresis, where the fast-migrating free ssDNA is separated from the slow-migrating D-loops, allowing precise quantitation of the proportion of oligonucleotide found in the product D-loop. The deproteinization sidesteps the requirement of the DNA-strand transferase to release its product. Since the plasmid is covalently closed, the amount of DNA-strand exchange that can occur (heteroduplex DNA tract length) is limited by topological constraints. The dsDNA must be supercoiled for productive D-loop formation, as it aids DNA-strand transferase filament-mediated dsDNA unwinding and stabilizes the D-loop during gel electrophoresis.

The DNA-Strand Exchange Assay

Similar to the D-loop assay, the three-strand DNA exchange assay (Figure 4(c)) detects plectonemic joint molecules formed by DNA-strand transferases. However, the ssDNA substrate is relatively long (5.4 kb for the frequently used phiX174 virion form DNA) and circular, while the dsDNA partner is linear and of the same sequence (phiX174 Replication Form I). Consequently, the region of DNA-strand exchange can now be very long, up to the entire length of the DNAs.

First, DNA-strand transferase filaments are formed on the ssDNA with the help of the cognate ssDNA-binding protein to remove secondary ssDNA structure. Then, the dsDNA is added and the homology is aligned, likely via the formation of a paranemic joint. Prerequisite to the appearance of products on agarose gels, a plectonemic joint molecule forms, starting with DNA intertwining one strand of a dsDNA end with the incoming ssDNA to begin strand exchange. Lastly, polar branch migration extends the heteroduplex region around the circle, until DNA-strand exchange is complete, with nicked circular dsDNA

and displaced linear ssDNA as final products. Upon deproteinization of the reactions followed by agarose gel electrophoresis, two product species can be distinguished – joint molecules and nicked circles. The linear ssDNA product usually cannot be resolved from the circular ssDNA substrate. The joint molecules include all plectonemes that have begun but not completed strand exchange, whereas the nicked circles represent the product with the maximum extent of heteroduplex DNA.

Single DNA Molecule Studies

The development of techniques to track single DNA molecules and to visualize recombination proteins acting on them has advanced our understanding of DNA-strand transferase filament nucleation, growth, and disassembly. Study at the single-molecule level eliminates the averaging and consequent loss of information that results from experiments that employ a large ensemble of molecules. Many different techniques have the sensitivity to gain information on single molecules of DNA. One classical method employed to study DNA-strand transferases involves the use of linear DNA (usually linear 48-kb lambda dsDNA) end-bound to a 1- μm -diameter bead. The bead is held in place inside of a multi-channelled flow cell by an optical trap. By moving the stage, the bead and bound DNA can be transferred into different channels within the flow cell, thereby changing buffer conditions or adding additional proteins. Nucleoprotein filament formation, stability, and disassembly can be monitored by chemically labeling the DNA-strand transferase with a fluorophore. Alternatively, the DNA end opposite the bead is labeled with a fluorophore and DNA-strand transferase binding is monitored by the movement of the fluorophore that results from the extension of the DNA that accompanies DNA-strand transferase binding. Single-molecule approaches to study DNA-strand transferases are still in the early phase of their development, but have already provided unprecedented insights into their function.

DNA-Strand Transferases in Signaling and Translesion Synthesis

Although DNA-strand transferases perform a primary function in the mechanism of HR, they are also involved in other cellular processes, including DNA damage signaling and translesion DNA synthesis. In *E. coli*, the SOS damage response is dependent on the RecA-ssDNA filament to act as a coprotease to cleave and deactivate the LexA repressor. This, in turn, leads to the expression of many derepressed genes (SOS operon) required for the damage response. Independent of the SOS signaling function, RecA protein is also required for translesion DNA synthesis by DNA polymerase V. In *S. cerevisiae*, a single unrepairable DSB leads to a checkpoint-mediated G(2)/M arrest, but a phenomenon termed adaptation allows the cell cycle to resume even in the presence of the DSB. Adaptation requires Rad51 protein through an unknown mechanism involving its interaction with Rad52 protein. Thus, it appears that eubacteria and eukaryotes have evolved feedback mechanisms to monitor the status of DNA-strand transferase filaments as a way to assess genotoxic stress conditions.

Glossary

Crossover An exchange of genetic information either side of a double-strand break (DSB) during homologous recombination (HR).

Double holliday junction (DHJ) dissolution A reaction catalyzed by BLM/TopoIII α /RMI1 that results in a DHJ being processed into exclusively non-crossover products.

DSB DNA double-strand break.

Holliday junction (HJ) A four-stranded DNA HR intermediate.

Homologous recombination (HR) A process of DSB repair that utilizes homologous DNA sequence as a template for high-fidelity repair.

Late replication intermediate (LRI) It occurs when two replication forks converge.

Nonhomologous end joining (NHEJ) A DSB repair pathway that rejoins the broken DNA ends in a process that

does not require sequence similarity and is therefore error prone.

Sister chromatid exchange (SCE) A form of HR that can be visualized in metaphase cells and results from reciprocal exchange of genetic information between sister chromatids.

Synthesis-dependent strand annealing (SDSA) It can occur following the early invasion step of HR when a D-loop is extended and is then able to be annealed to the other end of the DSB due to sequence homology.

Topoisomerase An enzyme that catalyzes a DNA-strand passage event, either by creating a break in one strand of the DNA helix (type I) or by creating a DSB (type II), allowing another DNA strand to pass through.

Ultrafine bridge (UFB) A DNA bridge that can be visualized in cells during anaphase by staining with antibodies against BLM/TopoIII α /RMI1, but cannot be stained with conventional DNA dyes such as DAPI.

Introduction

Helicases are enzymes that utilize the energy derived from adenosine triphosphate (ATP) hydrolysis to separate the complementary strands of a DNA or RNA duplex. They are found in all organisms and their strand-separating action is essential for a wide range of biological processes, including DNA replication, transcription, and repair, as well as various aspects of RNA metabolism.

DNA helicases have been classified into superfamilies based on their sequence similarity. The two largest superfamilies, SF1 and SF2, share a characteristic helicase domain that is composed of seven motifs: I, Ia, II, III, IV, V, and VI. Motifs I and II make up the highly conserved Walker A and B boxes that are conserved in many ATPases. SF1 and SF2 include both DNA and RNA helicases.

Helicases can also be classified according to the directionality of their translocation along DNA/RNA. These enzymes often require a region of single-stranded DNA (ssDNA) to bind to, before initiating unwinding of an adjacent region of the duplex. The helicase enzyme then translocates unidirectionally along the ssDNA, coupling displacement of the complementary strand of the duplex with ATP hydrolysis. The directionality is defined by whether the enzyme translocates 3'–5' or 5'–3' along this ssDNA.

The distance that a single helicase molecule is able to travel along the DNA during the unwinding reaction is termed the 'processivity' of the enzyme, and it differs considerably among different helicases. The processivity and DNA-substrate specificity of a helicase can be enhanced by a number of factors. Additional domains outside of the helicase domain may promote binding to different DNA substrates and hence unwinding. Protein-binding partners and subsequent protein-complex

formation may stimulate the unwinding activity of the helicase. Moreover, posttranslational modifications may affect the processivity of unwinding.

Structural and biochemical studies have provided insight into the mechanism of DNA unwinding by helicases. The favored model is the 'inchworm' mechanism in which the helicase, either monomeric or oligomeric, acts in a manner analogous to that of a snow plough, translocating along the DNA, possibly one base pair at a time, and separating the DNA strands using a wedge-like structure to peel apart the DNA strands. The details of this mechanism vary between helicases but require the protein to be able to bind simultaneously to both ssDNA and duplex DNA at some point during the reaction. The alternative 'rolling-circle' mechanism assumes that the helicase acts as a multimer, with a conformational change occurring following or during ATP hydrolysis that stimulates the ability of the helicase to separate the DNA duplex.

The RecQ helicases are a family of 3'–5' helicases belonging to SF2. They are highly conserved through evolution and have been shown to play an important role in maintaining the stability of the genome. This family of helicases is discussed in more detail in this article.

RecQ Helicases

RecQ helicases are very well conserved throughout evolution, from prokaryotes to eukaryotes, with the number of RecQ helicases expressed in a given organism often correlating with the size of the genome; cells with larger genomes, such as in mammals, often express several, while unicellular organisms, such as yeast or bacteria, express one or sometimes none (Figure 1). This family is named after the prototypical member

Figure 1 Comparison of the domain architecture of RecQ helicases. Colored areas represent conserved domains including the helicase domain (orange), RQC domain (blue), HRDC domain (red), and exonuclease domain (green).

in *Escherichia coli*, RecQ. The central helicase domain, containing the Walker A and B box motifs, is the defining feature of all RecQ helicases and is essential for the binding and hydrolysis of ATP. Surrounding domains differ between the various RecQ family members, but there is commonly an RecQ C-terminal domain (RQC domain) and a helicase and RNase D C-terminal domain (HRDC domain) present. The RQC domain is specific to RecQ helicases and is located immediately C-terminal to the helicase domain. It is composed of two subdomains, a so-called winged-helix motif, and a zinc-binding region, the combination of which is responsible for DNA binding and hence determining the substrate specificity of the different enzymes. The HRDC domain is also usually C-terminal to the helicase domain, but is not found in all RecQ helicases. The HRDC domain is also considered to play a role in mediating protein–DNA interactions. Other motifs are also present in some RecQ helicases; for example, the human WRN protein has an exonuclease domain. Posttranslational modifications, such as phosphorylation and sumoylation, play a central role in the regulation of activity of RecQ helicases.

Humans have five RecQ helicases, designated BLM, WRN, RecQ1, RecQ4, and RecQ5, all of which share the highly conserved central helicase region but differ in their ancillary domains. The main interest in RecQ helicases stems from the discovery that mutation in three of these human RecQ helicases leads to defined genetic disorders that result in human disease such as premature aging and cancer; mutation of BLM causes Bloom’s syndrome (BS), mutation of WRN leads to Werner’s syndrome (WS), and mutation of RecQ4 causes Rothmund Thomson syndrome (RTS). One common feature of each of these human RecQ disorders is their association with an increase in cancer predisposition. RecQ proteins therefore act as genome caretakers, protecting the genome from deleterious

changes that might cause tumor formation; lack of a RecQ helicase causes genome instability and an increased likelihood of oncogenic activation.

Yeast model systems have been used extensively to study the function of RecQ helicases. Sgs1 in *Saccharomyces cerevisiae* and Rqh1 in *Schizosaccharomyces pombe* have the characteristic domains seen in most RecQ helicases, including the central helicase domain, the RQC domain, and the HRDC domain. Yeast-deletion mutants of RecQ helicases provide a relatively quick way to investigate the genetic interactions between RecQ helicases and other pathways of DNA metabolism. The high level of conservation between yeast and human RecQ helicases suggests that the functions of these proteins are evolutionarily conserved, likely making findings in yeast applicable to human proteins as well.

RecQ Helicases and DNA Repair

The faithful replication of genetic information during the cell cycle is essential for cell viability. Failure to maintain the fidelity of DNA replication can result in chromosomal aberrations, such as translocations and deletions, which can promote tumorigenesis. Cells are constantly exposed to agents that damage DNA both from endogenous sources, such as free radicals generated within the cell, and from exogenous sources, such as ultraviolet light or chemicals. To combat this damage, cells have evolved numerous DNA repair pathways, which ensure that the DNA is repaired before the damage is replicated and transferred to daughter cells. RecQ helicases are a family of proteins that play a role in this maintenance of genome integrity by stabilizing damaged replication forks to prevent their irreversible demise.

A type of DNA damage that is particularly detrimental to the cell is the DNA double-strand break (DSB). DSBs can arise in the cell during DNA replication, when a replication fork encounters damage and collapses, or can occur directly following exposure to ionizing radiation. DSBs can be repaired by two major pathways in human cells: homologous recombination (HR) and nonhomologous end joining (NHEJ). HR is usually an error-free process of repair because it utilizes a homologous DNA sequence such as a sister chromatid. RecQ helicases have been shown to play a major role in suppressing recombination to ensure that illegitimate or aberrant recombination does not occur.

Bloom's Syndrome

BS is caused by loss of function of the protein BLM. BS is an extremely rare, autosomal recessive disorder, affecting less than 1 in 10 million people. The clinical phenotype of BS patients includes dwarfism, type II diabetes, immunodeficiency, reduced fertility, and a predisposition to the development of all types of cancers. It is this susceptibility to the range of cancers seen in the human population that makes the study of BS and the BLM protein of such interest to cancer researchers. Cells from BS patients have a number of hallmark characteristics including sensitivity to drugs that inhibit DNA replication and an increase in the level of sister chromatid exchanges (SCEs), a marker used in the diagnosis of the disease. SCEs are thought to arise via a form of HR and are usually aphenotypic as the two sister chromatids should have an identical DNA sequence. However, if SCE occurs unequally, or between nonidentical sequences, loss of heterozygosity can arise, leading to an increase in the likelihood of tumorigenesis if this occurs in tumor-suppressor genes. The presence of BLM is therefore required to limit this hyper-recombination phenotype. Inherited nonsense or frameshift mutations in the *BLM* gene usually lead to the production of a nonfunctional truncated BLM protein, which may be degraded or which is unable to undergo its normal cellular functions, thereby contributing to genome instability and subsequent cancer formation.

The BLM Protein

The BLM protein is an ATP-dependent 3'–5' DNA helicase that requires a short region of ssDNA to bind to before translocating in a 3' to 5' direction, and displacing the complementary strand. It has been shown *in vitro* that its preferred substrates are forked structures, two types of HR intermediates (DNA displacement loops (D-loops) and four-way Holliday junction (HJ) structures), and G-quadruplex DNA, a noncanonical DNA structure that can form in guanine-rich DNA (Figure 2). Besides being able to unwind these various DNA structures, BLM is also able to perform the opposite function, that of annealing complementary DNA strands together. This strand-annealing activity is independent of ATP hydrolysis; indeed, it cannot occur in the presence of ATP, and therefore the relevance of this annealing activity *in vivo* is as yet not clear. BLM is also able to branch-migrate the HJ recombination intermediate.

Figure 2 (a) Examples of DNA substrates for RecQ helicases. From top, left to right, a 3'-single-stranded DNA overhang; a forked duplex; a bubble structure; a Holliday junction; a displacement loop; and G-quadruplex DNA. (b) An example of the helicase activity of recombinant BLM protein. BLM is able to unwind a forked duplex into single-stranded DNA in a concentration-dependent manner. The asterisk represents the radiolabeled 5' phosphate.

BLM Binding Partners

BLM interacts with a number of proteins *in vivo*. It carries out many of its biological functions in conjunction with topoisomerase III α (TopoIII α), a type IA topoisomerase that has the ability to catalyze DNA-strand passage by creating a break within a region of ssDNA and rejoining this break once another DNA strand has been passed through it. BLM also forms a complex with a protein called RMI1 to form the BLM/TopoIII α /RMI1, or BTR, complex. Rmi1 has no detectable enzymatic activity of its own, but the presence of RMI1 stimulates the enzymatic activity of BLM and TopoIII α via a direct interaction between RMI1 and TopoIII α . A fourth component of the complex, RMI2, is considered to enhance the stability of the BTR complex, but has no effect on the enzymatic activity of BLM. BLM has also been shown to interact with the ubiquitous ssDNA-binding protein, replication protein A (RPA). RPA is a heterotrimeric protein essential for DNA replication and therefore cell survival. RPA can stimulate the DNA-unwinding activity of BLM.

In cell biological assays, BLM has been shown to localize to distinct nuclear foci following replication stress. These foci are thought to represent sites of DNA damage as many proteins involved in the DNA damage response colocalize there, including the key HR protein, Rad51, and the BRCA1 and Fanconi anemia proteins. The presence of BLM in these foci suggests a role for BLM in the replication-stress response, possibly by maintaining the integrity of stalled replication forks.

S. cerevisiae Sgs1

Many of the BLM–protein interactions seen in human cells are conserved in yeast. The budding yeast RecQ helicase, Sgs1, is most similar to the human RecQ helicase BLM, with many of the cellular features of BS cells being recapitulated in *sgs1 Δ*

cells. Like the hyper-recombination phenotype observed in BS cells, *sgs1Δ* cells have an increase in the level of recombination. Similarly, *sgs1Δ* cells are sensitive to drugs that inhibit DNA replication. Sgs1 also binds Top3 and Rmi1, the yeast orthologs of human TopoIII α and RMI1.

Werner's Syndrome

WS is an autosomal recessive disease caused by mutation of the *WRN* gene. WS is associated with premature aging and an increased likelihood of cancer. Cells from WS patients divide a limited number of times and enter senescence much earlier than normal cells, making cellular studies challenging. This premature senescence could provide the basis for the aging phenotype seen in WS patients. WS cells display an increased number of aberrant chromosomes, such as translocations and deletions, and are sensitive to replication inhibitors and DNA cross-linking agents.

The WRN protein not only contains the characteristic features seen in RecQ helicases, but also has a 3'-5' exonuclease domain that is similar to the exonuclease domain of *E. coli* DNA polymerase I. Most mutations in *WRN* result in the formation of a truncated protein that is unable to translocate to the nucleus. The WRN protein catalyzes similar DNA-unwinding reactions to BLM. It can unwind forked structures, D-loops, HJs, and G-quadruplex DNA (Figure 2), and this helicase activity can be stimulated by RPA. Additionally, WRN, like BLM, can branch-migrate HJ substrates.

Rothmund Thomson Syndrome

RTS is an autosomal recessive disease caused by mutation of the *RecQ4* gene. The main symptoms of this disease are skeletal and skin abnormalities, developmental retardation, and a predisposition to the development of osteosarcoma. As with other RecQ-deficient syndromes, RTS cells display an increased frequency of chromosomal aberrations, including translocations and deletions, suggesting a role for RecQ4 in maintaining genome stability.

The RecQ4 gene product is unique among RecQ helicases in lacking both the RQC domain and an HRDC domain. RecQ4 has ATPase activity, but initial studies showed no detectable helicase activity on a wide range of substrates. However, it is able to anneal complementary ssDNA and has been proposed to play a role during replication via its interaction with core replication factors. More recent studies indicate that RecQ4 might even possess two separate helicase domains and activities, and bind to proteins required for replication initiation.

Mutations in *RecQ4* also cause two other human genetic disorders: RAPADILINO and Baller-Gerold syndrome. Neither of these diseases is associated with an increased risk of cancer development and they are phenotypically distinct from each other and RTS, although they do have in common some aspects of defective development, such as skeletal malformation.

Anti-Recombinogenic Actions of RecQ Helicases

As mentioned earlier, the classical feature of cells from BS patients is a high level of spontaneous SCE. This suggests that

the presence of BLM is required to suppress this form of recombination. Similarly, *sgs1Δ* cells show an increase in recombination events, a feature that can be reversed following deletion of the key HR gene *RAD52*. The suppression of HR by RecQ helicases has been demonstrated in a number of ways. In biochemical assays, BLM and WRN have been shown to disrupt two structures that form early in HR, the Rad51 filament and the D-loop. In HR, following the formation of a DSB, an exonuclease resects the break to reveal a 3' ssDNA overhang (Figure 3). The Rad51 recombinase binds to this 3' ssDNA overhang and catalyzes invasion of this strand into homologous dsDNA, resulting in the formation of a D-loop. BLM has been shown to disrupt this Rad51 filament formation, thereby limiting HR. Strand invasion generates a D-loop. One possible outcome for a D-loop is that the invading ssDNA can be extended far enough to become a template for the so-called synthesis-dependent strand annealing (SDSA) pathway. This process does not involve an HJ intermediate and requires unwinding of the extended D-loop. BLM can catalyze D-loop unwinding, thereby facilitating SDSA and preventing crossover formation. Crossover products only form following HR during DSB repair and are defined by the exchange of the genetic material on either side of the break site, which can be deleterious to the stability of the genome. An alternative outcome for a D-loop involves the formation of HJ (Figure 3). If the second strand of the DSB is captured, a double Holliday junction (DHJ) will be formed. HJs can be resolved in prokaryotes and eukaryotes by HJ resolvases. These HJ resolvases make symmetrical nicks on two of the four strands of the HJ, which is followed by a ligation step. Resolvases create both crossover and non-crossover products with equal frequency, depending on the orientation of the nicks. In biochemical experiments using an oligonucleotide-based DHJ substrate, BLM and TopoIII α were also shown to be able to act on this DHJ structure, and to dissolve the structure into exclusively non-crossover products. This so-called DHJ-dissolution activity is specific to BLM and TopoIII α , and requires the helicase domain and HJ branch-migrating ability of BLM and the strand-passage activity of TopoIII α . RMI1 stimulates DHJ dissolution by interacting with TopoIII α and enhancing its strand-passage function. This DHJ dissolution activity of BLM could be one way in which BLM prevents crossing over and hence SCE.

WRN interacts with a number of proteins involved in DNA recombination and repair, including Ku70/Ku80, a heterodimeric protein complex that is essential for NHEJ, an error-prone pathway of DSB repair. The binding of the Ku complex to WRN stimulates the exonuclease activity of WRN. Lack of WRN in cells results in larger deletion tracts during NHEJ, suggesting a role for WRN in limiting NHEJ by either processing or stabilizing the DNA ends.

Pro-Recombinogenic Roles of RecQ Helicases

RecQ helicases can clearly play a role in many of the steps of HR, with most of these roles leading to suppression of recombination. However, recent data have shown that BLM and Sgs1 are able to affect one of the earliest steps of HR, the formation of the 3' ssDNA overhang. Initial processing of the DSB ends

Figure 3 Schematic of the homologous recombination pathway of DSB repair. The RecQ helicases can act a number of steps within this process to limit crossover formation. BLM can disrupt Rad51 filament formation on the 3'-ssDNA overhang thereby preventing HR. BLM and WRN can unwind D-loop structures, a process that is required for synthesis-dependent strand annealing (SDSA) and produces only non-crossover products. Alternatively, if the second double-strand break (DSB) end has been captured and a double Holliday junction (DHJ) is formed, BLM can ensure that exclusively non-crossover products are generated by catalyzing DHJ dissolution in conjunction with TopoIII α and RMI1.

requires the Mre11–Rad50–Nbs1 complex (Mre11–Rad50–Xrs2 complex in yeast) and CtIP (Sae2 in yeast). Biochemical evidence using purified BLM protein indicates that BLM promotes 5' end resection over long distances by stimulating Exonuclease I (Exo I), thereby activating HR. However, in yeast, Sgs1 has been shown to be able to catalyze this resection step independently of Exo I, and through stimulating the activity of another exonuclease, Dna2, to promote 5' end resection. This role for BLM and Sgs1 in promoting the early resecting step of HR seems to be at odds with the recombination suppression action of RecQ helicases, but this discrepancy could be resolved if the resection catalyzed by BLM channels repair through SDSA, a process that gives exclusively non-crossover products.

RecQ Helicases in Meiosis

Studies in yeast have revealed an important role for RecQ helicases in a scheduled DSB repair process that occurs during meiosis. Genetic diversity is essential for evolution and is generated in meiosis during the exchange of genetic information between homologous chromosomes, termed 'crossing over'. Unlike in mitotically dividing cells, crossing over is promoted in meiosis. This genetic exchange is initiated by a programmed DSB that is processed into a DHJ structure. The Mus81–Mms4/Eme1 enzyme complex is an HJ resolvase responsible for

resolving at least some of these DHJs into crossover products during meiosis. In *S. cerevisiae*, *sgs1 Δ mus81 Δ* double mutant cells are synthetically lethal (i.e., they are unable to survive), suggesting a role for Sgs1 in meiotic recombination. These *sgs1 Δ mus81 Δ* cells are unable to separate their chromosomes during meiosis, presumably because some recombination structures remain unresolved in the absence of both Sgs1 and Mus81.

Roles of RecQ Helicases during Replication

RecQ helicases function during replication to maintain genome stability. One way in which they may do this is by unwinding roadblocks in the DNA that may otherwise cause replication fork (RF) stalling or collapse. BLM and WRN have been shown *in vitro* to be able to unwind non-B form DNA, such as G-quadruplex DNA, which forms in guanine-rich regions of the genome, thereby allowing replication to proceed unhindered. WRN is also able to unwind telomeric DNA that might form G-quadruplexes. Telomeres protect the end of the chromosome from being recognized as a DSB by the cellular DNA repair machinery. They are made up of the repetitive sequence (TTAGGG) which is 2–10 kb in length, with a 3' ssDNA tail at the very end. This tail is able to loop back and invade the telomeric sequence, creating a so-called t-loop, thereby protecting the DNA end. The 3' ssDNA tail is a substrate for telomerase, a specialized reverse transcriptase that is

able to maintain the length of the telomere during replication. WRN has been shown to be necessary to unwind these t-loops to allow replication of the telomeres to occur. In the absence of telomerase, cells maintain the length of their telomeres by the alternative lengthening of telomeres (ALT) pathway. In ALT, the 3' ssDNA end of a shortened telomere invades double-stranded telomeric DNA and uses this as a template for HR-mediated elongation. The source of the dsDNA is controversial but may be the same or another chromosomal end, or an extrachromosomal telomeric circle. *S. cerevisiae* cells lacking telomerase components have been shown to senesce earlier than wild-type cells. A very small proportion of these cells are able to escape senescence by utilizing an Sgs1-mediated HR pathway of ALT.

An additional role for BLM during replication was recently shown to be the restart of stalled RFs. RFs stall when they encounter a block in the DNA such as a DNA secondary structure, protein–DNA complexes, or specific DNA damage such as a DNA cross-link or nick. Stalled RFs have the potential to collapse, resulting in a single-ended DSB that is dependent on HR for repair. BLM has been shown to be able to stabilize stalled RFs and ensure replication progression, an activity that is dependent on the helicase activity of BLM and phosphorylation of a specific threonine residue on BLM (Thr 99), which is the target for the stress-activated kinase ATR.

Biochemical evidence has also indicated that BLM is able to catalyze RF regression (Figure 4). Fork regression is one way in

which stalled RFs can be stabilized, preventing their collapse. It occurs when the nascent DNA strands at an RF (which are complementary) are unwound from the parental strands and anneal to each other, creating a four-way junction analogous to an HJ. Once the regressed fork has been formed, the RF is stabilized to allow time for repair processes to remove or bypass the blocking lesion. BLM can restart replication either by direct reversal of the regressed fork or by forming a DHJ. Again, the helicase domain of BLM is required for this fork-regression activity. Theoretically, fork regression will only occur if the RF-stalling lesion is present on the leading strand. If the lesion is present on the lagging strand, a gap will be left in the nascent DNA that can be either filled postreplicatively or filled by recombination-mediated gap repair via DHJ formation (Figure 4). DHJ dissolution by BLM/TopoIII α will ensure that crossovers, and potential genome instability, do not occur.

S. cerevisiae has been used extensively to study RF stalling and recovery within a cell population. Treatment of *sgs1 Δ* , *top3 Δ* , or *rmi1 Δ* cells with the drugs hydroxyurea (HU, depletes nucleotide pools leading to RF stalling) or methylmethanesulphonate (MMS, an alkylating agent that damages DNA and causes DNA polymerase stalling) causes increased cell death compared to wild-type cells. A technique called two-dimensional gel electrophoresis can be used to analyze a specific region of DNA in yeast cells and has revealed that *sgs1 Δ* cells contain unresolved, X-shaped recombination intermediates following MMS exposure. A yeast strain carrying mutations

Figure 4 Potential roles for RecQ helicases in replication fork (RF) stability. (Left) If a lesion (green star) is encountered on the leading strand of an RF (a), leading and lagging strand polymerases may become uncoupled, allowing lagging strand DNA synthesis to continue. (b) RF regression, possibly catalyzed by BLM/WRN/Sgs1, allows template switching to occur with the nascent lagging strand acting as a template for leading strand synthesis. The RF can be restored either by DHJ formation (c) and DHJ dissolution, potentially catalyzed by BLM/TopoIII α /RMI1 (d), or by direct reversal of the regressed fork (e). The RF is maintained and the damage can be removed by specialized repair pathways. (Right) If an RF encounters damage on the lagging strand (A), replication is able to continue past the lesion due to the discontinuous nature of lagging strand synthesis. The resulting gap can be filled in by specialized polymerases that are able to synthesize across damaged DNA through a process termed 'translesion synthesis' (B), or a DHJ can be formed allowing the nascent lagging strand to use the nascent leading strand as a template (C). The RF can be restored following DHJ dissolution by BLM/TopoIII α /RMI1 (D).

in *SGS1* and the gene encoding the essential HR protein, Rad51, no longer contain these unresolved HR intermediates, indicating that Sgs1 is involved in the removal of these structures in a recombination-dependent manner.

Another role for RecQ helicases during replication has been suggested from studies using *E. coli* RecQ. A key question in cell biology is on how replication is completed when two RFs converge during S phase. These late replication intermediates contain intervening DNA that is yet to be replicated. By reconstituting *E. coli* DNA replication using purified proteins, it was shown that RecQ, together with Top3 and the ssDNA-binding protein SSB, is able to resolve this late replication structure via a decatenation reaction. The resulting ssDNA regions on both chromatids can then be filled in by the replicative polymerase. A similar reaction using BLM, TopoIII α , and RPA, the orthologous proteins in humans, may provide a similar result.

RecQ Helicases in Mitotic Cell Division

Studies using human cells have revealed the presence of DNA bridges that connect the separating sister chromatids during the anaphase of mitosis. These bridges are believed to represent unreplicated regions of chromosomes. Cells from BS patients have an increased frequency of these anaphase bridges, indicating that BLM has a role in ensuring the timely completion of DNA replication before the cells enter mitosis. Recently, a new class of anaphase bridges has been discovered, termed ultrafine bridges (UFBs). These UFBs can be stained along their length with antibodies against BLM, TopoIII α , and RMI1, and their number increases in cells lacking BLM. These UFBs could represent late replication intermediates that have not been resolved before the cells enter mitosis.

Conclusion

Cellular and biochemical approaches, in yeast and human cells, have provided a wealth of information on RecQ helicases in recent years. By identifying interacting proteins and revealing the activities of these enzymes, we have begun to understand how they function in the maintenance of genome stability. Their roles in suppression of illegitimate recombination and in maintaining the stability of stalled RFs are clearly crucial to ensure genome integrity and prevent tumorigenesis.

Glossary

Regulated intramembrane proteolysis (RIP) A process of signal transduction in which a membrane-bound protease cleaves its substrate within the lipid bilayer, thus allowing the cleaved protein fragment to function at a new location.

Rhomboid A family of intramembrane serine-proteases involved in the regulated intramembrane proteolysis (RIP) of type 1 transmembrane proteins.

Signal peptide peptidase (SPP) A family of intramembrane aspartyl-proteases involved in the RIP of type 2 transmembrane proteins.

Site-2 protease (S2P) An intramembrane metalloprotease involved in the RIP of type 2 transmembrane proteins.

γ -Secretase A protein complex containing an intramembrane aspartyl-protease catalytic subunit involved in the RIP of type 1 transmembrane proteins.

Regulated intramembrane proteolysis (RIP) is a newly recognized mechanism for signal transduction that involves the generation of regulatory molecules from membrane proteins. Such cleavage liberates cytoplasmic or luminal/extracellular fragments from transmembrane precursor proteins, allowing the cleaved fragments to function at a new location. RIP influences processes as diverse as cellular differentiation, lipid metabolism, immune defense, and the response to unfolded proteins, as originally addressed in a review article by Brown et al. In addition to its occurrence in animal cells, RIP has been observed in lower organism including bacteria, and, remarkably, the bacterial proteases are related evolutionarily to the ones used in animal cells. Proteins that are known to undergo RIP span the membrane bilayer at least once. The intramembrane cleavage of RIP is mediated by four different families of membrane-bound proteases: site-2 protease (S2P), γ -secretase, signal peptide peptidase (SPP), and rhomboid. Except for the RIP mediated by rhomboid, the intramembrane cleavage does not take place until the bulk of the protein on the extracytoplasmic (luminal or extracellular) face has been removed by a primary cleavage. This primary cleavage shortens the extracytoplasmic segment to less than 30 amino acids, which is a prerequisite for the secondary intramembrane cleavage. Numerous proteins are currently known to undergo RIP. In this article, we only discuss the RIP whose regulations and physiological/pathological importance are well characterized (Figure 1).

RIP Mediated by S2P Family

S2P is a polytopic membrane protein with the characteristics of a membrane-embedded zinc metalloprotease. Genes similar to the one encoding mammalian S2P have been identified in DNA sequences from multiple species, including archaea, bacteria, plants, and animals. The encoded proteins share a similar hydrophobicity profile that predicts a highly hydrophobic structure with multiple membrane-spanning regions. The NH₂-terminal portion of all of these proteins contains a sequence conforming to the HExxH consensus that is found in a large subfamily of zinc metalloproteases (where x is

typically a noncharged amino acid). In these proteins, the two histidines of the HExxH motif coordinate with a zinc atom, and the glutamate activates a water molecule, allowing it to make a nucleophilic attack on the peptide bond. Unlike its location in hydrophilic domains of classic zinc metalloproteases, the HExxH sequence of S2P is embedded in a highly hydrophobic segment. In addition to the HExxH motif, classic zinc metalloproteases contain a remote residue (tyrosine or aspartate) that provides an additional coordination bond for the zinc. In the S2P-like proteins, this function is believed to be filled by the aspartate of the amino acid sequence LDG, which also resides in a hydrophobic segment.

The crystal structure of the *Methanocaldococcus jannaschii* S2P, an archaeal S2P ortholog, provides a strong piece of evidence that S2P is indeed an intramembrane protease. The structure shows that the HExxH and LDG motifs are indeed embedded in transmembrane helices. The zinc ion, coordinated by the histidines in the HExxH motif and the aspartate in the LDG sequence, is sunk ~14 Å into the membrane from the cytosolic face. However, the active site surrounding the zinc ion is hydrated by a narrow water channel lined with polar residues including backbone carbonyls and charged side chains. These observations suggest that water molecules are capable to be delivered to the intramembrane active sites to catalyze the proteolytic reaction.

Proteins Cleaved by S2P in Animal Cells

The transmembrane helices cleaved by S2P adopt a type 2 orientation, that is, the NH₂-terminus of the transmembrane helices faces cytosol.

In animal cells, S2P is known to cleave three families of membrane-bound transcription factors: sterol regulatory element-binding proteins (SREBPs), activation transcription factor 6 (ATF6), and cAMP responsive element-binding protein 3 (CREB3). All of these proteins contain two conserved asparagine or proline residues in the middle of the transmembrane domain, located COOH-terminal to the cleavage site. These residues are required for S2P-catalyzed cleavage. They may serve as an NH₂-terminal cap that allows a portion of the

Membrane protein	Organism	Primary cleavage enzyme	Enzyme mediating rip	Regulator of cleavage	Sites of cleavage	Function or consequence of cleaved protein
<i>Rip by S2P family of proteases</i>					Extracytosolic Membrane Cytosolic	
SREBP	Mammals/ <i>drosophila</i>	S1P	S2P	Sterols/ phospholipids		Activates genes for lipid metabolism
ATF6	Mammals	S1P	S2P	ER stress		Activates genes for ER chaperones
CREB3L1	Mammals	S1P	S2P	BMP2		Activates transcription of collagen in osteoblast
CREB3L3	Mammals	S1P	S2P	IL-6		Activates genes for acute phase response
RseA	<i>E. coli</i>	DegS	YaeL	Unfolded proteins		Releases σ^E , which activates stress-induced genes
cAD1	<i>E. faecalis</i>	Signal peptidase	Eep	?		Stimulates mating
pro- σ^k	<i>B. subtilis</i>	None	SpoIVFB	SpoIVB		Activates genes for sporulation

Figure 1 Membrane proteins that undergo regulated intramembrane proteolysis (RIP) categorized according to the RIP protease. The cleaved protein fragments are highlighted in red. For simplicity, proteins are not drawn to scale, and we do not show the alternate pathway for APP processing, which involves cleavage by TACE. For Notch, we show only the transmembrane subunit.

transmembrane α -helix to unwind partially to expose the peptide bond for cleavage by S2P.

Sterol regulatory element-binding proteins

SREBPs are membrane-bound transcription factors that regulate the synthesis of cholesterol, a major component of membranes in mammalian cells. As shown in **Figure 1**, SREBPs are inserted in membranes of the endoplasmic reticulum (ER) in a helical hairpin fashion. The cytosolic NH₂-terminal domain is

a transcription factor of the basic-helix-loop-helix-leucine zipper family. The COOH-terminal domain, also cytosolic, forms a complex with a polytopic membrane protein called Scap. When cells are overloaded with sterols, the Scap/SREBP complex is trapped in the ER owing to its interaction with Insig proteins, which are also polytopic ER membrane proteins. The ER retention of SREBPs prevents their cleavage as proteases that cleave SREBPs reside in the Golgi complex. Upon deprivation of sterols, Scap is dissociated from Insig proteins, a reaction

allowing Scap to transport SREBPs from the ER to Golgi, where cleavage occurs. Inasmuch as SREBPs activate genes encoding enzymes of cholesterol synthesis, this sterol-mediated block in transport allows cholesterol to inhibit its own synthesis in a classic feedback fashion.

The first cleavage of SREBPs is catalyzed by site-1 protease (S1P), a membrane-bound serine protease that is oriented with its active site in the lumen of the Golgi complex. Cleavage by S1P separates the two transmembrane helices of SREBPs, but the NH₂-terminal fragment remains membrane bound until it is cleaved by S2P at a site that is three residues within the transmembrane segment (Figure 1). Even though the activity of S2P is not regulated directly by sterols, S2P does not act until the two transmembrane segments have been separated by S1P, which effectively brings this reaction under cholesterol control.

In *Drosophila*, orthologs of SREBP, Scap, S1P, and S2P are all expressed even though *Drosophila* cells do not produce sterols. *Drosophila* SREBP is processed by S1P and S2P in a reaction that requires Scap and presumably requires ER to Golgi transport. The major SREBP targets in *Drosophila* S2 cells are enzymes required for synthesis of saturated fatty acids, which are incorporated into the major phospholipid, phosphatidyl ethanolamine (PE). PE, rather than sterols, is the feedback regulator of SREBP cleavage in these cells.

Activation transcription factor 6

ATF6 is a type 2 membrane protein with a single transmembrane domain (Figure 1). Its NH₂-terminal cytosolic domain is a transcription factor of the bZIP family. Under resting condition, ATF6 is not cleaved as it is retained in the ER through its association with an ER chaperon, BiP. Upon accumulation of unfolded proteins in the ER, ATF6 is dissociated from BiP. Consequently, ATF6 is translocated from the ER to Golgi, where it is cleaved sequentially by S1P and S2P, the same proteases that process SREBP. The intramembrane proteolysis carried out by S2P liberates the NH₂-terminal domain of ATF6 from the membrane, allowing it to activate transcription of *BiP* and other genes whose products assist the folding of ER proteins. This regulatory pathway, called the unfolded protein response, helps cells to survive conditions of ER stress.

ATF6 β is a close homolog of ATF6 in mammalian cells. It is also cleaved by S1P and S2P in response to ER stress, but the cleaved nuclear form does not activate transcription of genes that facilitate folding of proteins in the ER. Instead, the cleaved nuclear form of ATF6 β inhibits transcription of genes activated by the nuclear form of ATF6 in a dominant negative manner. Thus, ATF6 β may serve as a transcriptional repressor functioning in part to regulate the strength and duration of ATF6 activity during the ER stress response.

cAMP responsive element-binding protein 3

There are five proteins (CREB3, CREB3-like 1 (CREB3L1), CREB3L2, CREB3L3, and CREB3L4) that belong to the CREB3 transcription factor family in mammalian cells. Similar to ATF6, all of them contain a single transmembrane helix with an NH₂-terminal cytosolic domain resembling a transcription factor of the bZIP family. Among these proteins, only the functions of CREB3L1 and CREB3L3 are characterized.

CREB3L1, also named as OASIS, plays an important role in bone development. In response to bone morphogenetic

protein-2 (BMP-2), a cytokine required for bone formation and osteoblast differentiation, CREB3L1 in osteoblast is cleaved sequentially by S1P and S2P. The cleaved NH₂-terminal fragment then enters the nucleus to drive transcription of *coll1a1*, the major collagen found in bone matrix (Figure 1). Cleavage of CREB3L1 can also be stimulated by drugs triggering ER stress in cultured cells. However, whether RIP of CREB3L1 is also activated by ER stress *in vivo* remained to be determined.

CREB3L3, also named as CREB-H, is exclusively expressed in livers. It plays an important role in innate immunity by producing acute phase proteins. Microbial infection stimulates the production of pro-inflammatory cytokines such as interleukin-6 (IL-6) by leukocytes. IL-6 induces ER stress in hepatocytes, which in turn triggers the RIP of CREB3L3 by S1P and S2P. The cleaved NH₂-terminal nuclear form then activates transcription of C-reactive protein and other acute phase proteins in livers (Figure 1). These acute phase proteins are then secreted out of livers to provide early defense against microbial infection.

Proteins Cleaved by S2P in Bacteria

RseA

The RIP of RseA in bacteria is closely related to the RIP of mammalian ATF6. In *Escherichia coli*, σ^E is the transcription factor that regulates extracytoplasmic stress response. Under nonstress conditions, σ^E is negatively regulated by RseA, an inner membrane protein with one transmembrane domain (Figure 1). The NH₂-terminal cytosolic domain of RseA binds to σ^E and is sufficient to inhibit σ^E activity. When unfolded proteins accumulate in the periplasmic space (similar to ER lumen in eukaryotic cells), RseA is first cleaved by DegS, a membrane-bound serine protease with its active site projecting into the periplasmic space. Cleavage by DegS removes the majority of the COOH-terminal periplasmic domain of RseA. YaeL, an ortholog of S2P, then cleaves the remaining part of RseA, after which RseA is rapidly degraded. This frees σ^E to associate with RNA polymerase and direct transcription of its target genes.

The similarity between mammalian and bacteria unfolded-protein response suggests that S2P-mediated RIP has been selected to cope with extracytoplasmic stress during evolution, although individual organisms use the mechanism in different ways: in mammalian cells RIP directly releases the active transcription factor from its substrate, whereas in bacteria RIP leads to degradation of a membrane-bound inhibitor of the responsible transcription factor.

cAD1 precursor

Enterococcus faecalis, a Gram-positive bacterium, secretes an eight-amino-acid peptide pheromone called cAD1, which induces a mating response in other enterococci that harbor a plasmid called pAD1 (Figure 1). Genomic sequencing revealed that the octapeptide pheromone is derived from a 143-amino-acid precursor that contains a signal peptide at the NH₂-terminus and is inserted into the plasma membrane with a type 2 orientation. The pheromone corresponds to the COOH-terminal eight amino acids of the signal peptide (Figure 1). The octapeptide is generated by cleavage of the

precursor at two sites, at the extracellular side of the membrane in a reaction carried out by signal peptidase and at a site in the middle of the transmembrane signal peptide by Eep, an S2P ortholog. This system differs from the others in that the active fragment is released by S2P into the extracellular space rather than the cytosol.

Pro- σ^K

Another prokaryotic relative of S2P is a *Bacillus subtilis* protein called spoIVFB. This protein contains an HExxH and an LDG motif in hydrophobic segments, but the overall hydrophobicity profile of SpoIVFB differs from those of the other family members. SpoIVFB is the protease that removes a membrane-embedded NH₂-terminal hydrophobic peptide from a transcription factor, pro- σ^K , thereby releasing the factor into the cytosol and allowing it to activate gene transcription. This process is necessary for completion of spore formation in response to nutrient deprivation. The membrane orientation of pro- σ^K is opposite to the type 2 orientation of other known S2P substrates, and it is the only S2P substrate that does not require a primary cleavage (Figure 1). These differences in catalytic requirements may account for the differences in structure between SpoIVFB and the other members of the S2P family.

RIP Mediated by γ -Secretase

γ -Secretase is a membrane-bound complex consisting of several proteins, including presenilin, nicastrin, anterior pharynx-1, and presenilin enhancer-2 protein. In mammalian cells, there are two presenilin isoforms encoded by separate genes: presenilin-1 and presenilin-2. These two proteins are highly homologous and they function redundantly in γ -secretase-mediated RIP. Presenilin contains two conserved aspartate residues that are located in two of its nine transmembrane helices at positions that are predicted to place them at the same depth in the membrane. This property is reminiscent of soluble aspartyl proteases, which contain two closely apposed aspartates that are required for activity. Experiments with active-site-modifying agents specific for aspartyl proteases provide evidence that presenilin contains the active proteolytic site. Thus, presenilin is considered to be the catalytic subunit in γ -secretase.

γ -Secretase cleaves transmembrane helices that adopt the type 1 topology, that is, the COOH-terminus of the transmembrane segments exposes to cytosol. Numerous proteins are cleaved by γ -secretase. Three of them will be discussed here in detail to illustrate the RIP mediated by γ -secretase.

Amyloid Precursor Protein

Amyloid precursor protein (APP) is a type 1 membrane protein with an NH₂-terminal extracellular domain and a COOH-terminal cytosolic tail (Figure 1). Processing of APP generates a toxic amyloid β peptide that is responsible for Alzheimer's disease. APP is first cleaved at a site that is 28 amino acids from the transmembrane helix by β -secretase, a membrane-bound aspartyl protease with an extracytoplasmic active site. This cleavage shears off the bulk of the extracellular domain of

APP, which then allows the protein to be cleaved within the membrane by γ -secretase. Intramembrane cleavage can occur at either of the two sites separated by two amino acids, leading to two different amyloid β peptides, designated A β _{1–40} and A β _{1–42}, which accumulate extracellularly. After the intramembrane γ -secretase cleavage, the cytosolic tail of APP enters the nucleus where it may affect transcription of genes.

In addition to cleavage by β -secretase, APP can be cleaved by tumour necrosis factor α (TNF α) converting enzyme (TACE), a membrane-bound metalloprotease, whose active site faces the extracellular surface. TACE cuts the extracytosolic domain of APP even closer to the membrane, leaving only 12 amino acids on the external surface. Like the β -secretase cleavage, TACE cleavage is followed by γ -secretase cleavage. In this case, the liberated fragment is too short to form an amyloid deposit, and thus cleavage by TACE does not lead to Alzheimer's disease.

Notch

The cell-surface receptor Notch is synthesized as a type 1 membrane protein (Figure 1) that is processed constitutively by a furin-like enzyme in the secretory pathway. The enzyme cleaves the precursor to generate two subunits: an extracellular subunit and a transmembrane subunit, which remain associated as a noncovalent heterodimer. The heterodimer travels to the cell surface and remains intact until it binds its ligand Delta, a membrane protein that resides on the surface of an adjacent cell. Binding leads to cleavage of the transmembrane subunit of Notch by TACE, the same enzyme that cleaves APP. TACE cleavage releases most of the extracellular portion of the transmembrane subunit of Notch along with the attached extracellular subunit. The shortened transmembrane subunit is then cleaved by γ -secretase within the membrane-spanning helix, liberating a cytosolic fragment. The cytosolic fragment translocates to the nucleus where it activates several genes whose products influence the fate of cells during development.

ErbB-4

ErbB-4 is a transmembrane receptor tyrosine kinase that regulates cell proliferation and differentiation. It adopts a type 1 orientation with an NH₂-terminal extracellular ligand-binding domain and a COOH-terminal cytosolic tyrosine kinase domain (Figure 1). Upon binding to its ligand, heregulin, the ErbB-4 ectodomain is cleaved by TACE, followed by intramembrane proteolysis carried out by γ -secretase. The intramembrane cleavage results in the release of the cytosolic fragment, which travels to the nucleus where it phosphorylates substrates that regulate cell growth.

RIP Mediated by SPP

Five human SPPs have been identified: SPP, SPPL2a, SPPL2b, SPPL2c, and SPPL3. SPPs are remotely homologous to presenilin. They also contain two conserved aspartate residues that form the catalytic active site within the predicted transmembrane domains. However, topology studies revealed that the orientation of these transmembrane regions is inverted related

to that of presenilin. As a result, SPPs cleave type 2 membrane proteins instead of type 1 membrane proteins, which are cleaved by presenilin. While SPP and SPPL3 locate in the ER, SPPL2a and SPPL2b reside in endosomes and lysosomes. The difference in their localization is consistent with the findings that these proteases do not share the same substrates.

The best-studied example of RIP mediated by SPP is the proteolytic processing of signal peptides from MHC class I molecules such as HLA-A, -B, -C, and -G. These molecules are expressed with a typical signal sequence for targeting to the secretory pathway. During their translocation through the ER membrane, the signal sequences are cleaved off from the pre-protein by signal peptidase. The cleaved signal peptides, which remain membrane-bound with a type 2 orientation, are then cleaved by SPP in the middle of the membrane to liberate the NH₂-terminal half of the signal peptides into the cytosol (Figure 1). These cytosolic fragments are then transported into the ER lumen where they bind to HLA-E, a nonclassical MHC class I molecule. The HLA-E/peptide complexes travel to the cell surface where they bind to cluster of differentiation 94 (CD94) receptors on natural killer (NK) cells and inhibit NK cell-mediated lysis. This pathway protects cells expressing normal MHC class I molecules from killing by NK cells.

SPP is also involved in the maturation of core protein encoded by hepatitis C virus (HCV). The core protein corresponds to the first 169 amino acids of the viral polyprotein. It is localized at cytosolic side of the ER membrane and is linked to the remainder of the viral protein via a signal peptide-like transmembrane sequence at its COOH terminus. After cleavage by signal peptidase in the ER lumen, SPP cleaves the signal peptide-like transmembrane domain. Consequently, core protein is released from the ER and binds to lipid droplet where it plays an important role in assembly of viral particles.

SPPL2a and SPPL2b play an important role for activated dendritic cells to produce interleukin-12 (IL-12). Upon activation by Lipopolysaccharide, dendritic cells produce TNF α that is anchored to plasma membrane with a type 2 orientation (Figure 1). Following cleavage by TACE to shed the majority of the extracellular domain, SPPL2a/b cleaves inside the transmembrane domain to release the intracellular domain of TNF α from membranes, allowing it to enter the nucleus to activate transcription of IL-12. IL-12 secreted from activated dendritic cells promotes differentiation of T-helper 1 (Th1) cells and is essential for the induction of Th1-mediated adaptive immunity.

RIP Mediated by Rhomboid

Apart from S2P, rhomboid is the only other intramembrane protease whose crystal structure has been solved. Rhomboid is an atypical serine protease that contains a serine and histidine catalytic dyad. It does not have the third aspartic residue in the active site to form the catalytic triad, which is the signature for most serine proteases. The structure shows that the active site of rhomboid is embedded in the transmembrane domains. The catalytic serine locates at the bottom of a funnel-shaped cavity that is lined with polar residues and opens to outside of a cell. This structure ensures that water is accessible for the intramembrane cleavage reaction.

Rhomboid belongs to a large gene family that is conserved throughout archaea, bacteria, yeast, plants, and animals, including humans. The function of rhomboid homologs in bacteria has only been determined for AarA in Gram-negative bacterium *Providencia Stuartii*. AarA is a protein required for bacteria intercellular signaling known as 'quorum sensing'. The substrate for AarA is TatA, which contains a single transmembrane domain at its NH₂-terminus (Figure 1). Cleavage within the transmembrane domain by AarA is required for the activation of TatA, allowing the protein to form a channel that exports proteins across the bacterial membrane into the periplasm for signaling.

In eukaryotic cells, rhomboids are divided into two major subfamilies: secretase rhomboids, which reside in the secretory pathway, and PARL-type rhomboids, which locate in mitochondrial. To date, secretase rhomboid has only been characterized in *Drosophila* where it initiates epidermal growth factor receptor (EGFR) signaling. Spitz is the main ligand for *Drosophila* EGFR. It is synthesized as a transmembrane precursor with an NH₂-terminal extracellular EGF-like domain and a short COOH-terminus cytosolic tail (Figure 1). Spitz is confined to the ER and is inert until it binds to another protein named star. Star escorts spitz from ER to Golgi where spitz is cleaved by rhomboid. The intramembrane cleavage liberates the extracellular EGF-like domain from the membrane, allowing it to be secreted out of the cell.

The functions of mitochondrial rhomboids have been characterized in both yeast and mammalian cells. In yeast, the major substrate for the mitochondrial rhomboid, Rbd1, is Mgm1, a dynamin-like GTPase. Mgm1 is required to maintain the proper mitochondria morphology, and this function requires both the full length protein inserted into inner mitochondrial membrane and a processed form located in the intermembrane space. The full-length Mgm1 is inserted into the inner mitochondrial membrane through a single transmembrane domain, with its NH₂ and COOH-terminus residing in intermembrane space and mitochondrial matrix, respectively (Figure 1). Interestingly, the Rbd1 cleavage site is not in this transmembrane domain. Instead, it is located in a secondary hydrophobic site that is initially located in the intermembrane space. With the energy provided by ATP hydrolysis, mitochondrial import motor pulls the original transmembrane domain out of the inner membrane into the matrix, allowing the secondary hydrophobic domain to be inserted into the membrane. This cleavage mechanism is thought to provide an opportunity to regulate the balance between the processed and full length Mgm1 in response to mitochondrial membrane potential, which provides the energy source for the shifting in the transmembrane segment.

Mgm1 is the yeast homolog of the mammalian protein Optic Atrophy 1 (OPA1). However, OPA1 is not a good substrate for mammalian mitochondrial rhomboid presenilins-associated rhomboid-like protein (PARL). Rather than maintaining the mitochondrial morphology, PARL controls apoptosis, and this function is achieved by its cleavage of HtrA2. HtrA2 is synthesized as an inactive precursor inserted into mitochondrial inner membrane in a way similar to the yeast Mgm1. Cleavage by PARL releases the NH₂-terminal fragment of HtrA2 into intermembrane space (Figure 1). This processed form of HtrA2 inhibits apoptosis by preventing the accumulation of activated

Bax, which initiates apoptosis. The site where HtrA2 is cleaved by PARL is outside the transmembrane domain, suggesting that the cleavage mechanism employed by PARL may be similar to that used by Rbd1 to cleave Mgm1.

Glossary

Energy homeostasis The homeostatic regulation of energy balance.

Intermediary metabolite An intermediary step in a metabolic process.

Knockout mouse Term used for the homologous recombination and inactivation of an endogenous gene.

Neuropeptides Small protein signaling molecules secreted by neurons to facilitate endocrine neural communication.

Nutrient sensing The direct sensing and signaling by nutrients in contrast to endocrine signaling.

Introduction

Malonyl-CoA is a key intermediary metabolite in fatty acid synthesis. In *de novo* fatty acid synthesis, malonyl-coenzyme A (CoA) is the substrate that provides the primary carbon source for the formation of palmitate (C16) catalyzed by fatty acid synthase (FASN). Malonyl-CoA acts also as an allosteric inhibitor of carnitine palmitoyltransferase-1 (CPT1) and therefore fatty acid oxidation. The role of malonyl-CoA and fatty acids has been very well defined in lipogenic tissues. The role of *de novo* lipogenesis in the brain has been largely overlooked as the brain primarily utilizes glucose as its energy source and does not store energy in the form of lipid. Furthermore, neurons are thought to have little capacity for fatty acid oxidation. Our understanding of the neural fatty acid metabolism has been challenged by emerging data that suggest a new role for these molecules in the brain. Areas within the central nervous system (CNS), in particular, the hypothalamus, can sense peripheral circulating glucose and lipids and respond to fluctuations in these nutrients by modifying food intake or peripheral energy expenditure via altering the malonyl-CoA concentration.

Regulation of Cellular Fatty Acid Metabolism

In lipogenic tissues such as the liver, *de novo* lipogenesis is regulated by the activity of acetyl-CoA carboxylase (ACC). ACC, the rate-limiting and highly regulated step, carboxylates acetyl-CoA to form malonyl-CoA in an adenosine triphosphate (ATP)-consuming step. ACC is positively regulated by the tricarboxylic acid (TCA) intermediate citrate, which is also the carbon source for cytoplasmic acetyl-CoA after cleavage by ATP:citrate lyase. ACC is inhibited by phosphorylation by adenosine monophosphate (AMP)-activated protein kinase (AMPK). The activity of AMPK is enhanced by the binding of AMP and is highly responsive to the ratio of AMP:ATP. Therefore, when cellular energy is in deficit, fatty acid synthesis is turned off.

The product of ACC, malonyl-CoA, is used by FASN as the chain elongation unit for the reiterative reductive biosynthesis of long-chain fatty acids. Malonyl-CoA serves another important regulatory role in fatty acid metabolism by

allosterically inhibiting CPT1. CPT1 is the rate-limiting step in the oxidation of long-chain fatty acyl-CoAs as it regulates the entry of fatty acyl-CoAs into the mitochondrial matrix. The dual roles of malonyl-CoA as the carbon source for *de novo* fatty acid synthesis and inhibitor of oxidation ensure the proper regulation of fatty acid metabolism. In other words, malonyl-CoA provides the metabolic logic for fatty acid metabolism.

Humans with mutations in the liver isoform of CPT1, CPT1a, result in an inability of the liver to efficiently buffer blood glucose via gluconeogenesis. The oxidation of long-chain fatty acids in the liver upon fasting also enables the production of ketone bodies to provide energetic substrates for neural metabolism during prolonged fasting. Fatty acid oxidation in muscle is used as a primary energy source in the absence of insulin-stimulated glucose uptake. Muscle does not, however, have the ability to produce fatty acids *de novo* due to the lack of FASN. Muscle expresses a unique CPT1, CPT1b, and a unique ACC, ACCbeta. ACCbeta performs the same enzymatic reaction and is regulated in a similar fashion as the liver isoform, ACCalpha. The main difference is that ACCalpha is a soluble cytoplasmic enzyme and ACCbeta is tethered to the outer mitochondrial membrane and therefore juxtaposed to CPT1b. Therefore, the function of ACC and malonyl-CoA in muscle is solely to regulate the oxidation of exogenous fatty acids. To deplete and regulate malonyl-CoA, as no FASN exists, muscle expresses malonyl-CoA decarboxylase to decarboxylate malonyl-CoA to acetyl-CoA and CO₂.

The Hypothalamus Is Important for the Control of Food Intake and Energy Homeostasis

The control of energy homeostasis is critical for the maintenance and survival of any organism. Disruptions in energy homeostasis can often lead to chronic disease states. When energy intake exceeds expenditure, fatty acids in the form of triacylglycerol are stored in adipose tissue. Intricate control systems have evolved to maintain energy homeostasis by inhibiting food intake and increasing energy expenditure during periods of energy excess and increasing food intake and decreasing energy expenditure during lean times. More recently, the

mammalian CNS has garnered much attention as a site that regulates the energy-sensing needs of an organism by altering hunger/satiety and communicating this need directly via neural circuits to peripheral energy centers to mediate fuel utilization.

The hypothalamus is the specialized region within the brain which contains distinct nuclei to control energy homeostasis and food intake. Other areas of the brain also contribute to the control of energy homeostasis. Chemical, genetic, or physical lesioning of the hypothalamus results in severe deficiencies in body weight regulation. The arcuate nucleus, ventral medial nucleus, and paraventricular nucleus among others have been identified as the key centers that respond to changes in energy status by modifying the expression of specific neuropeptides that alter food intake and energy expenditure. Also, the alteration of synaptic connectivity in the hypothalamus has been shown to be an important component in body weight regulation. The hypothalamus can respond to circulating endocrine hormones including leptin, ghrelin, and insulin, secreted by peripheral tissues. The hypothalamus contains at least two distinct neuronal populations that integrate these circulating cues. One set of neurons express the orexigenic (feeding promoting) neuropeptides such as agouti-related protein (AgRP) and neuropeptide Y (NPY). The second neuronal population within the hypothalamus expresses the anorexigenic (feeding inhibiting) neuropeptides, such as alpha melanocyte-stimulating hormone (alpha MSH), and the cocaine and amphetamine-related transcript (CART). The paradigm follows: when energy intake exceeds expenditure, the expression of NPY and AgRP neuropeptides decrease and alpha MSH and CART increase; when energy expenditure exceeds intake, the expression of CART and alpha MSH neuropeptides increases and NPY and AgRP decreases. The first-order neurons in the hypothalamus are under the primary control of circulating hormones, and integrate signals to higher brain centers where this information is integrated and behavioral responses are formulated.

The Role of Central FASN in Regulating Body Weight

Fatty acids can be imported into the brain through passive diffusion across the blood-brain barrier or generated through *de novo* synthesis. The interest in fatty acids playing a role in food intake and energy expenditure arose from the discovery that inhibitors of FASN, C75 and cerulenin, cause a dramatic weight loss in animal studies. These inhibitors rapidly induce a reduction in food intake and body weight loss in obese mice. These inhibitors were efficacious for models of diet-induced obesity (DIO) and genetic forms of obesity such as the leptin (*ob/ob*) or leptin receptor (*db/db*) mutant mice. Elucidation of the mechanism of FAS inhibitors is of great interest in the development of pharmacological targets to counter obesity.

The effect of the inhibitors is rapid and suppresses food intake in less than 20 min. Long-term (30-day study) administration of a low-dose treatment of *ob/ob* mice resulted in an almost complete reversal of obesity. FASN inhibition studies have shown that central or peripheral administration rapidly affects the levels of hypothalamic neuropeptides that regulate feeding behavior. Concomitant with a decrease in food intake

is a decrease in the feeding promoting neuropeptides, NPY/AgRP, while levels of the food-inhibiting POMC/CART neuropeptides increase (POMC, proopiomelanocortin). These inhibitors were found to rapidly inhibit NPY production in the arcuate nucleus of mice even after 23 h of fasting, usually a time when NPY production is highly upregulated to stimulate food intake.

FASN has been shown to colocalize with NPY neurons in the hypothalamus. The loss of the FASN gene via homologous recombination is lethal with even heterozygotes showing a loss of viability. A conditional loss of function allele was made and FASN was specifically deleted from the hypothalamus. These mice phenocopied the effects of the inhibitor. The mice were hypophagic, lean, and had altered neuropeptide expression. Furthermore, these mice also exhibit an increase in energy expenditure mediated by an increase in activity. FASN inhibitors can further affect weight loss by increasing energy expenditure and whole-body oxygen consumption. Pair feeding experiments in which control mice are restricted to the intake of FASN inhibitor-treated mice demonstrate that treated mice lose more weight; they increase their energy expenditure in peripheral tissues, as measured by whole-body calorimetry studies. Central administration of FASN inhibitors to lean or obese mice rapidly activates fatty acid oxidation in skeletal muscle, therefore mediating a major impact in whole-body energy expenditure.

Hypothalamic Malonyl-CoA

Inhibiting FASN either pharmacologically or genetically reduces body weight. The inhibition of FASN causes an increase in its substrate malonyl-CoA. Since malonyl-CoA serves a signaling role in muscle, it was hypothesized that malonyl-CoA could be serving a signaling role in the hypothalamus to regulate body weight. Indeed, the simultaneous inhibition of ACC and FASN reverses the weight-reducing effects of FASN inhibitors. Furthermore, exogenous addition of malonyl-CoA decarboxylase to the hypothalamus results in an increase in body weight. Finally, malonyl-CoA is dynamically regulated by meal state. Fasting suppresses hypothalamic malonyl-CoA and refeeding causes a spike in hypothalamic malonyl-CoA concentration. These experiments strongly suggest that malonyl-CoA is a major nexus for the regulation of body weight (Figure 1).

Regulation of Hypothalamic Malonyl-CoA

The concentration of malonyl-CoA fluctuates between periods of nutritional surplus and shortage. The initial signal for this

Figure 1 Phenotypic outcomes of modulating *de novo* fatty acid synthesis in the CNS. Inhibition of FASN results in weight loss, and promoting malonyl-CoA decarboxylation results in weight gain. Loss of CPT1c results in mice with a reduction in food intake and weight loss.

Figure 2 The regulation of hypothalamic malonyl-CoA. ACC is regulated by citrate as an allosteric activator and inhibited by AMPK phosphorylation. Glucose flux through the mitochondria produces both citrate and ATP. A high AMP:ATP ratio activates AMPK activity while a low AMP:ATP ratio is inhibitory. AMPK activity can also be modulated by anorexogenic and orexogenic endocrine molecules such as leptin and ghrelin.

nutrient-sensing pathway appears to be through the modulation of AMP-dependent protein kinase (AMPK) activity. AMPK differentially binds two molecules of AMP or ATP. ATP-bound AMPK is inactive while the AMP-bound form is activated by upstream kinases. Coupled with the action of adenylate kinase, the AMP:ATP ratio serves as a biochemical signal for AMPK. Changes in the hypothalamic AMP:ATP ratio and AMPK activity via differential nutrient paradigms impact feeding behavior and body weight, although it remains unclear what the cell-type-specific effect is. There is also cross-talk between endocrine signaling pathways in the hypothalamus such as leptin, ghrelin, and adiponectin and the nutrient-sensing pathway as all of these molecules effect AMPK activity. AMPK was first characterized as the kinase responsible for phosphorylating and thus inhibiting ACC and HMG-CoA reductase (HMG-CoA, 3-hydroxy-3-methylglutaryl-coenzyme A). Therefore, AMPK inhibits the rate-limiting steps in the synthesis of fatty acids and cholesterol. During times of low cellular energy, synthesis is inhibited. ACC catalyzes the biotin-dependent carboxylation of acetyl-CoA to malonyl-CoA in the highly regulated and committed step in fatty acid synthesis. Therefore, the activity of AMPK directly impacts the concentration of malonyl-CoA. Hypothalamic malonyl-CoA concentration serves as a satiety signal and is directly proportional to the activity of AMPK and ACC (Figure 2).

Carnitine Palmitoyltransferase-1c

Malonyl-CoA is essential for the regulation of mitochondrial fatty acid beta oxidation due to its role as an allosteric inhibitor of CPT1 enzymes. Neurons do not robustly oxidize fatty acids and most neurons have a low level of CPT1a and CPT1b. Neurons do have, however, a neuron-specific CPT1 gene, CPT1c. CPT1c is expressed throughout the brain and is expressed in

hypothalamic nuclei known to be important for body weight regulation. CPT1c binds malonyl-CoA at a K_d equivalent to CPT1a, but does not catalyze acyl transfer to carnitine. In fact, CPT1c is not localized to mitochondria, but is integral to the endoplasmic reticulum. Therefore, it has been hypothesized that CPT1c performs a novel enzymatic reaction that is essential to controlling body weight. When CPT1c is knocked out in mice, they have a low body weight and reduced food intake. This is consistent with CPT1c being the target of malonyl-CoA in the hypothalamus that controls body weight. Furthermore, it was shown that CPT1c knockout (KO) mice are susceptible to weight gain on a high fat diet and exhibited reduced whole-body energy expenditure. Taken together, malonyl-CoA regulation of CPT1c represents a new signaling paradigm in body weight regulation.

Conclusion

The control of body weight by intermediary metabolites of fatty acid biosynthesis is a new concept in nutrient signaling. Malonyl-CoA serves as a central signal in the CNS to convey organismal energy status and modify body weight accordingly. The *in vivo* physiologic role of this pathway has been established with nutrients and endocrine signals playing regulatory roles. Hypothalamic malonyl-CoA concentration can be affected by glucose concentration through modulating AMPK activity or by endocrine signals such as leptin and ghrelin. The mechanism by which malonyl-CoA effects change in body weight are in part through modulating the novel neuron-specific CPT1c. Finally, this newly identified pathway provides new therapeutic targets for the treatment of obesity.

Regulation of Chromatin Dynamics

E-J E Hong and C L Peterson, University of Massachusetts Medical School, Worcester, MA, USA

© 2013 Elsevier Inc. All rights reserved.

Glossary

Bromodomain A distinct protein domain that is found in chromatin-related proteins in a variety of organisms from mammals to yeast. Bromodomain binds specifically to acetylated lysine residues on histone proteins.

Chromatin Name given to the DNA–protein complex present in the nucleus of eukaryotic cells.

Chromodomain The chromatin-organization-modifier domain, a conserved region of ~60 amino acids, originally identified in *Drosophila* modifiers of variegation. Recent studies indicate that this domain binds specifically to methylated lysine residues on histone proteins.

Nucleosome The repeating unit of chromatin composed of DNA wrapped around a histone octamer consisted of two copies each of H2A, H2B, H3, and H4.

Chromatin Basics

Eukaryotic genomes are organized by a set of positively charged proteins called histones. Two copies of four histones, H2A, H2B, H3, and H4, form an octamer by hydrophobic interaction through their histone-fold domains. Each octamer wraps around 147 bp of DNA (~1.8 turns) to form the basic unit of chromatin called the nucleosome. Each nucleosome has eight amino-terminal tails (one from each histone) and two carboxyl-terminal tails (one from each H2A) that protrude out of the core region. These tails are targets of posttranslational modifications that regulate nucleosome dynamics. In higher eukaryotes, linker histones (H1 and H5) bind to the entry–exit point of the nucleosomes, which can contribute to the stability of nucleosomes by preventing unwrapping of deoxyribonucleic acid (DNA). Nucleosomes complexed with linker histones are called chromatosomes, and they are prominent in highly condensed regions of a chromosome.

Different organisms and cell types show distinct spacing between nucleosomes. Average nucleosome spacing ranges from 10 to 50 bp. *In vitro*, an array of nucleosomes forms an extended, 10-nm fiber in low salt (e.g., tris with ethylenediaminetetraacetic acid (EDTA) (TE) buffer) that is cytologically visible as a beads on a string. In physiological ionic conditions (100 mM Na⁺, 1–2 mM Mg²⁺), an array of nucleosomes folds into a fiber of 30 nm in diameter. Linker histones stabilize the 30-nm fiber, and emerging works suggest that different lengths of linker DNA may alter the structure of the 30-nm fiber. Self-association of the 30-nm fibers has been proposed to lead to the formation of chromonema fibers with diameters ranging from 60 to 80 and 100 to 130 nm. Further condensation leads to thick 200–400 nm filaments that are characteristic of interphase chromatin. In addition, some regions of chromatin form a special structure called heterochromatin, whose underlying DNA is less accessible than those in euchromatin.

Nucleosomes provide a safe storage of long, linear DNA (2 m in human cells) and contribute to genomic integrity. However, the positional stability of nucleosomes limits the access of underlying DNA, and thus has an inhibitory effect on DNA metabolism that includes gene expression, repair of

DNA lesions, and DNA replication. To overcome this inhibition, cells utilize three strategies to change the packaging states of nucleosomes: (1) covalent modifications of histones, (2) incorporation of histone variants, and (3) ATP-dependent nucleosome remodeling (Figure 1). The interplay of these three mechanisms determines nucleosome dynamics and subsequent folding of chromatin, such that DNA is accessed/exposed in a regulated manner. The resulting eviction, movement, and/or restructuring of nucleosomes is called ‘chromatin remodeling’.

Covalent Modifications on Nucleosomes

Although covalent modifications are not limited to histone tails, the tails are rich with residues that are susceptible to various modifications. Lysines and arginines are subject to acetylation, methylation, citrullination, sumoylation, and ubiquitylation, whereas serines, threonines, and tyrosines are targets of phosphorylation.

Histone modifications may affect accessibility of DNA in three ways. First, they can change the physical properties of nucleosomes to alter the histone–DNA contacts. This could allow removal of nucleosomes by other proteins/remodelers more readily, and hence aid in creating a nucleosome-free region (NFR) over important *cis*-acting elements. Notably, histone tails do not make strong contributions to DNA–histone interactions within individual nucleosomes; so, this mechanism is more relevant to modifications within the core domains of the histones. Second, histone modifications can regulate chromatin folding and/or oligomerization of chromatin fibers by altering nucleosome–nucleosome interactions. Indeed, the histone tail domains are known to play essential roles in chromatin folding. Third, histone modifications can recruit/stabilize the binding of effector proteins that contain specialized domains that recognize defined chemical moieties. These effector domains are present in components of the transcription apparatus as well as structural/regulatory proteins that modulate chromatin structure. Notably, the effector domains are present in chromatin remodelers; thus, histone modifications can have a direct effect on recruitment of these proteins.

Figure 1 A diagram showing the dynamic interplay of histone modifications, histone variants, and ATP-dependent chromatin remodeling enzymes.

Acetylation

Histone acetylation involves the transfer of an acetyl moiety from acetyl-CoA to the ϵ -amino group of a lysine residue, resulting in neutralization of the positive charge. Yeast Gcn5 was the first nuclear acetyltransferase to be identified, and along with other histone acetyltransferases (HATs), p300 and PCAF, it functions as a transcriptional coactivator. Histone deacetylases (HDACs) remove the acetyl group from histones, and typically act as transcriptional repressors. Notably, establishment of heterochromatin in budding yeast requires removal of acetylation at H4K16 by a nicotinamide adenine dinucleotide (NAD)-dependent deacetylase silent information regulator 2 (Sir2). Thus, histone acetylation *in vivo* correlates with access to underlying DNA.

It has been proposed that the acetylation of certain internal lysines (e.g., H3K56) may affect nucleosome stability by reducing the affinity of histones for DNA. Although acetylation of histone tails does not affect nucleosome structure in a significant way, it may affect the mobility of nucleosomes by altering the interaction between the tail and the linker DNA. Acetylation also prevents folding of chromatin – a 10-nm nucleosomal array containing H4 that is homogeneously acetylated on lysine 16 shows a marked decrease in its ability to fold into a 30-nm fiber. Furthermore, H4K16Ac inhibits inter-fiber interaction and oligomerization of the nucleosomal arrays, which is thought to be a major way in which chromatin is organized in yeast. The H4 tail (16–20) interacts with the acidic patch on H2A of the neighboring nucleosome, and it is likely that the acetylation and subsequent charge neutralization of H4K16 disrupts its contact with H2A. In addition, the remodeling activity of the Imitation Switch (ISWI) protein (see next), which contributes to gene repression by facilitating regular spacing of nucleosomes, is attenuated by H4K16 acetylation.

Bromodomains are structural motifs that recognize acetylated lysines. Although the bromodomain has been shown to bind unmodified histone tails *in vitro*, this domain of 110–120 amino acids shows a strong preference for acetylated lysines. Structural studies of bromodomains by nuclear magnetic resonance and X-ray crystallography showed that this preference for acetylated lysines can be attributed to extra hydrogen bonds formed between the carbonyl oxygen of the acetyl group and the amino acid side chains that are present within the pocket of the four-helix bundle of bromodomains. The amino acid sequences following the acetylated lysine contribute to the specificity for different histone acetylations (e.g., H3K14Ac vs. H4K16Ac) by providing additional sites of interaction. The dissociation constant of a bromodomain for a single acetylated lysine shows relatively weak affinity (e.g., hTAF_{II}250 double bromodomain $K_d = 39 \mu\text{M}$ for H4K16Ac peptides); however, the presence of multiple acetylations can enhance affinity significantly (e.g., hTAF_{II}250 double bromodomain $K_d = 5.6 \mu\text{M}$ for H4K8Ac/H4K16Ac), demonstrating cooperation among multiple histone modifications. Bromodomains are important for gene expression, as they are present in many transcriptional activators and ATP-dependent chromatin remodelers that promote remodeled chromatin structures.

Methylation

Methylation involves transfer of a methyl group from S-adenosyl-L-methionine to lysine or arginine. Methylation/demethylation has been associated with a wide range of biological phenomena that include transcriptional regulation, heterochromatin formation, X-chromosome inactivation, as well as DNA methylation. Thus, methylation plays an important role in epigenetic regulation of the genome.

Most methylations are carried out by proteins that contain a highly conserved Su(var)3–9, Enhancer-of-zeste, Trithorax (SET) domain. However, the discovery that the Dot1/KMT4 methyltransferase, which targets H3K79, does not have a SET domain showed that methylation could be carried out via multiple mechanisms. Unlike acetylation, methylations occur in different states. Lysine methylation occurs in a monomethyl, dimethyl, or trimethyl state, whereas arginine methylations occur in monomethyl, asymmetric dimethyl, or symmetric dimethyl states. Different sites as well as different states lead to different readouts. Methylation at H3K4 correlates with active transcription, whereas H3K9 methylation is generally associated with gene repression. However, while H3K9me2/3 correlates with gene silencing in heterochromatin, H3K9me1 is seen over actively transcribed genes.

Methylation is decoded by different effector proteins that recognize the methylated moiety. One well-known example is the chromodomain. Chromodomains are typically 50–60 amino acids long and form an N-terminal, three-stranded, anti-parallel β -sheet packed against the C-terminal α -helix. A cleft between β 1 and β 3 creates a hydrophobic pocket composed of three aromatic residues (exact residues differ from mouse HP1 β to *Drosophila* Polycomb), to which the methylated lysine binds. Dissociation constants for chromodomains show a dynamic range – HP1 β bound to H3K9me2 peptide shows $K_d = 0.7 \mu\text{M}$, whereas Swi6 (HP1 of *Schizosaccharomyces pombe*) and Ctr4 (H3K9 methyltransferase in *S. pombe*) show $K_d = 10$ and $3 \mu\text{M}$, respectively. As is the case for acetylation, the dissociation constants displayed by chromodomains are in the μM range, and are not sufficient to recruit these proteins to modified nucleosomes. Thus, their recruitment may be mediated by other DNA-binding proteins, or by the combined affinity of multiple chromodomains for different histone modifications. Chromodomains do not recognize methylated lysine as a free amino acid, and the context within which the methylated lysine resides (i.e., the surrounding amino acids) is important for specificity. Similarly, the context within which the chromodomain resides within the histone tail is also important for recognition of different modifications. For example, the chromodomain of Polycomb binds to H3K27me2/3, whereas the chromodomain of heterochromatin protein 1 (HP1) binds to H3K9me2/3. Similarly, the chromodomain of human CHD1 binds to H3K4me2/3.

It was long believed that lysine or arginine methylation was an irreversible histone modification and that the only way to reverse this mark was by histone removal. However, the recent discovery of histone lysine demethylases suggests otherwise. Two classes of lysine demethylases exist to date: (1) lysine (K)-specific demethylase LSD1/KDM1 family and the (2) jumonji C domain-containing histone demethylase (JHDM) family. LSD1 oxidatively demethylates H3K4me and H3K9me using flavin adenine dinucleotide as a cofactor. The JHDM family represents a large class of demethylases (over 30 members in human) that contain a highly conserved jumonji C domain, which uses Fe(II) as a cofactor. *In vitro*, the rate of LSD1/KDM1-mediated catalysis is >200-fold faster than that of the JHDM family of demethylases, prompting a possibility that JHDM associates with unknown protein cofactors that may stimulate its activity *in vivo*.

Arginines are methylated by a large family of protein arginine methyltransferases, and are demethylated by either a

JHDM-like demethylase (JMJD6) or arginine deiminases (see later for citrullination). Arginine methylations have been implicated in nuclear-hormone-mediated transcriptional activation.

Phosphorylation

Phosphorylation appends a negatively charged phosphate moiety to the hydroxyl group of serines, threonines, or tyrosines. All four histones, as well as the linker histone H1, are targets of phosphorylation. Notably, histone H3 Ser10 is phosphorylated during mitosis, and this mark is associated with transcriptional activation, chromatin condensation, and mitotic progression. H3S10 phosphorylation provides a classic example of cross-talk between histone modifications. H3S10 phosphorylation occurs more readily on histones that are pre-acetylated at H3K14, and the coexistence of both marks is important for binding of the 14-3-3 effector protein to the phosphorylated moiety. The 14-3-3 protein then recruits the HAT MOF that acetylates H4K16. This event then results in recruitment of a bromodomain-containing BRD4 protein that brings the transcription elongation factor b, which aids in elongation of the RNA polymerase II. Thus, cooperation of multiple histone modifications works in concert to promote gene expression, providing multiple opportunities for regulation.

Similar cross-talk occurs for another binary methylation/phosphorylation switch. HP1 protein contains a chromodomain that binds to H3K9me2/3, and it plays an important role in transcriptional repression. When the nucleosome containing H3K9me2/3 and HP1 is phosphorylated at H3S10, it results in removal of HP1 proteins without altering the H3K9 methylation. This allows transcription of the underlying DNA without erasing the methyl mark, and may play an important role in transient transcription of the normally silent chromatin. Likewise, H3Y42 phosphorylation also excludes HP1 proteins from heterochromatin; thus, the mechanism by which multiple histone modifications modulate the effector proteins may be a common theme.

Ubiquitylation

Ubiquitylation is an unusual form of histone modification. Instead of a small chemical moiety, a 76-amino-acid-long peptide is attached to a lysine residue. Ubiquitylation occurs via sequential enzyme reactions: (1) ubiquitin-activating enzyme (E1) activates ubiquitin in an ATP-dependent manner, (2) activated ubiquitin is attached to a ubiquitin-conjugating enzyme (E2), and (3) ubiquitin is appended to the substrate using an E3 ubiquitin ligase as a scaffold that brings the E2 and the substrate in close proximity.

Histone H2B is ubiquitylated at K123 (K120 in higher eukaryotes) by a macromolecular complex containing Rad6 (E2) and Bre1 (E3) enzymes. H2B–K123 ubiquitylation is linked to transcriptional elongation, and it is reversed by ubiquitin proteases Ubp8 and Ubp10 in yeast. H2B–K123 ubiquitylation has served as another prime example of histone cross-talk, as this modification is required for H3K4 and H3K79 methylation.

Significantly more H2A (10–15%) is ubiquitylated than H2B (1–5%) in higher eukaryotes. H2A ubiquitylation is regulated by the polycomb group complexes, PRC1 and PRC2. The PRC2 complex interacts with the *cis*-acting element called polycomb response element, and methylates H3K27. H3K27me_{2/3} allows binding of the PRC1 complex, which contains an E3 ubiquitin ligase that mediates ubiquitylation at H2A–K119. H2A–K119ub results in enhanced loading of H1 to chromatin *in vitro* and *in vivo*, and subsequent formation of the chromatosome.

H3 is polyubiquitylated in rat-elongating spermatids, and this modification is thought to mediate degradation during the replacement of histones by transition proteins during spermatogenesis. In human cells, H3 and H4 are ubiquitylated by the CUL4–DDB–ROC1 complex, and this is thought to facilitate the cellular response to ultraviolet DNA damage by affecting nucleosome stability.

Sumoylation

Histone H4 is also sumoylated in human cells, and this mark is linked to gene silencing. Small ubiquitin-related modifier is 18% identical to ubiquitin, and slightly larger (11 kDa as opposed to 9 kDa). Sumoylated H4 is thought to contribute to gene silencing by recruiting HDACs and HP1. In budding yeast, all four histones are sumoylated. In particular, H2B–K6/K7, H2B–K16/17, H2A–K126, and five lysines on the H4 tail were identified as targets of sumoylation. H2B–K6/7/16/17A mutation leads to an increase in transcription at *TRP3*, *SUC2*, and *GAL1* by two- to threefold, suggesting that sumoylation is required for transcriptional repression at these loci. Sumoylation seems to occur throughout the genome, but is present at slightly higher level in sub-telomeric regions. It is hypothesized that sumoylation counteracts ubiquitylation and acetylation to inhibit transcription.

Citrullination

Peptidylarginine deiminases (PADs) convert arginine into a non-native amino acid citrulline. H2A, H3, and H4 are targets of citrullination. PAD4, which was first identified in human leukemia cells, can remove a methylated arginine by converting it into citrulline. This conversion has been shown to regulate genes that are targets of estrogen and p53, demonstrating a promoter-specific histone citrullination in gene regulation. Hypercitrullination of histones is also associated with chromatin decondensation in granulocytes/neutrophils, leading to speculation that it contributes to chromatin unfolding in a global manner.

Proteolysis

An unusual form of histone regulation is the regulation of histone-tail proteolysis. The H2A C-terminus is cleaved between Val114 and Leu115 during granulocyte differentiation. These cleaved H2A–H2B dimers display a lower affinity for H3–H4 tetramers, and this results in destabilization of the nucleosome. A similar phenomenon is observed in *S. cerevisiae*,

in which the N-terminus of H3 is cleaved prior to nucleosomal eviction from chromatin, suggesting that proteolysis promotes open chromatin structure by inducing histone turnover. During mouse embryonic stem-cell differentiation, 21–27 amino acids of the N-terminus of histone H3.2 is cleaved by a cysteine protease cathepsin L. The functional significance remains to be seen; however, such a mechanism could act as a rapid switch in erasing epigenetic marks.

Histone Variants

Histone variants are nonallelic isoforms of the canonical histones. Histone variants are expressed throughout the cell cycle, and their deposition into nucleosomes is not dependent on DNA replication or limited to S phase when canonical histones are incorporated into nucleosomes. As histone variants are also covalently modified, deposition of variants provides cells yet another layer of regulation in nucleosome dynamics.

Of the four core histones, the H2A histone has the most variants. As described above, H2A has an acidic patch that makes contact with the H4 tail of the neighboring nucleosome. This contact is important for nucleosome–nucleosome interactions that are required for chromatin folding. In H2A.Z, which shares ~60% identity to H2A, the acidic nature of this patch is increased. Consistent with this, H2A.Z stimulates the folding of nucleosomal arrays *in vitro*, while simultaneously inhibiting inter-fiber interaction. A crystal structure of an H2A.Z-containing nucleosome indicates a slight destabilization in the H2A.Z–H3 interaction, and the presence of a metal ion-binding pocket, which could affect linker histone binding. Insights from the crystal structure have also argued against the possibility of H2A.Z and H2A being in the same nucleosome. However, both homotypic (two H2A.Z–H2B dimers) and heterotypic (H2A–H2B and H2A.Z–H2B dimers) nucleosomes have been observed *in vivo*. The effect of H2A.Z on the stability of the nucleosome has been controversial, but one determining factor may be H3 – H2A.Z nucleosomes containing H3.3 are particularly unstable and salt-labile compared to those with H3.1 or H3.2. Thus, multiple variants may collectively determine nucleosome structure and stability. H2A.Z is incorporated into chromatin by the Swr1 complex (see next), and recent genetic evidence suggests that it may be removed by the Ino80 complex (see next). In yeast and humans, H2A.Z is present at the nucleosomes flanking the transcription start site, and it has been hypothesized that H2A.Z facilitates transcription. H2A.Z is monoubiquitylated at the inactive X chromosome of mammalian female cells, is sumoylated in *S. cerevisiae*, and is subject to multiple amino-terminal acetylations in many species.

H2ABbd is unique to mammals, and causes a significant change in nucleosome structure. Instead of 147 bp of DNA wrapping around a canonical octamer, nucleosomes containing H2ABbd wrap only 118–130 bp, resulting in a far less stable structure. H2ABbd lacks the C-terminal tail that contains the ubiquitylatable lysine residue and the acidic patch that interacts with histone H4. Consistent with this, nucleosomal arrays containing H2ABbd have reduced propensity to fold into 30-nm fibers *in vitro*. *In vivo*, H2ABbd is hypothesized to be associated with active chromatin.

MacroH2A is unique to vertebrates. While it has 64% identity to canonical H2A, it has a large nonhistone C-terminus, and is overall much larger in size than H2A. MacroH2A resides in heterochromatin, most notably in the inactive X chromosome of female mammals. MacroH2A confers resistance to chaperone-mediated histone exchange, ATP-dependent remodeling by SWItching defective/Sucrose NonFermenting (SWI/SNF), and RNAP II-dependent transcription; hence, macroH2A correlates with the closed chromatin state.

The H2A.X variant is present throughout genomes, at a density of ~ 1 H2A.X nucleosome per 10 H2A nucleosomes. H2A.X is quite similar to H2A, but contains a novel C-terminal motif (SQEL) that provides a site for phosphorylation. In budding yeast, the major form of H2A is similar in sequence to mammalian H2A.X. In response to formation of a DNA double-strand break (DSB), H2A.X is phosphorylated at a C-terminal serine residue (Ser139) by ATM, ATR, and DNA-PK kinases. H2A.X phosphorylation occurs over megabases of chromatin that flank a single DSB in mammalian cells (~ 50 kb in yeast), and is thought to provide binding sites for components of the DNA repair and cell-cycle checkpoint machineries.

Histone H3 has many variants: H3.1, H3.2, H3.3, and CENP-A. The H3.1 variant differs from H3.2 by one amino acid. H3.1 is considered to be the major H3, as it has the highest expression level. H3.2 is encoded by one gene (as opposed to 10 genes for H3.1), and H3.2 is enriched with repressive marks, such as H3K27me_{2/3} and H3K9me₂, suggesting that H3.2 may be enriched in heterochromatin. H3.3 differs from H3.1 by five amino acids, and is linked to active transcription, especially when in complex with H2A.Z. While incorporation of H3.1 and H3.2 to chromatin is coupled to replication, H3.3 is incorporated into chromatin by both replication-coupled and replication-independent mechanisms. CENP-A is a specialized H3 that is loaded at centromeres and provides a platform for kinetochore assembly. Human CENP-A has a less-flexible N-terminus compared to H3, and incorporation of CENP-A results in unwrapping of 7 bp of DNA near the entry/exit point. How these changes aid in assembly of special centromeric chromatin remains to be seen.

ATP-Dependent Nucleosome Remodeling

Remodeling enzymes use the energy from ATP hydrolysis to disrupt DNA–histone interactions. All remodeling enzymes contain at least one ATPase subunit and other subunits that determine the biological context, for example, subunits that determine the recruitment to specific loci, or those that regulate its ATPase activity. There are four families of remodeling enzymes, and they are classified by distinct features/domains within their ATPase subunit. They are the SWItching defective/Sucrose NonFermenting (SWI/SNF), chromodomain helicase DNA binding (CHD)/Mi-2, ISWI, and inositol requiring 80 (INO80) families.

SWI/SNF Family

SWI/SNF is one of the first chromatin remodeling complexes to be characterized. SWI/SNF is a multi-subunit complex

(11 subunits, ~ 1 MDa in yeast), whose members were initially identified in a genetic screen for positive regulators of transcription. It was later discovered that mutations in H3 and H4 (called the Switch INdependent (SIN) mutations) suppressed the transcriptional defects in SWI/SNF mutants, leading to the hypothesis that SWI/SNF modulates chromatin structure. Subsequent biochemical assays led to the discovery that SWI/SNF can disrupt nucleosomes. SWI/SNF can (1) reposition/slide nucleosomes translationally; (2) evict nucleosomes, albeit with low efficiency; and (3) evict H2A–H2B dimers on certain DNA templates (mouse mammary tumor virus).

In yeast, SWI/SNF and Remodeling Structure of Chromatin (RSC) represent this family of remodeling enzymes, and they are characterized by the following features on their ATPase subunits: DExx-HELICc ATPase domain with a short insertion, a bromodomain, and a Helicase-SANT-Associated (HSA) domain that interacts with actin-related proteins (ARPs). Genome-wide gene expression studies demonstrated that both SWI/SNF and RSC promote gene expression, and that they regulate largely nonoverlapping sets of genes. RSC is much more abundant than SWI/SNF, suggesting a broader role in chromatin metabolism. Consistent with this notion, RSC is essential for viability, while SWI/SNF is not. RSC is also required for chromosome segregation – RSC localizes to centromeres, and is required for kinetochore function. Moreover, RSC associates with chromosome arms in a cell cycle-dependent manner, and physically interacts with cohesin to promote sister chromatid cohesion.

Evolutionarily conserved set of complexes has been identified in higher eukaryotes. In flies, two complexes, BRM-associated proteins (BAPs) and polybromo-associated BAPs (PBAPs), share one ATPase subunit, Brahma. In mammals, Brg1/hBRM-associated factors (BAFs) and polybromo-associated BAFs (PBAFs) have distinct ATPase subunits (as in yeast) called hBRM and BRG1. Similar to their counterparts in yeast, SWI/SNF family members in higher eukaryotes promote transcription, although human SWI/SNF complexes have also been shown to facilitate transcriptional repression.

In *Drosophila*, subunits of SWI/SNF (Brahma, Moira, and Osa) are members of the Trithorax Group (TrxG) that antagonizes the transcriptional repressive effect of the Polycomb group proteins, in order to induce expression of homeotic (*HOX*) genes that specify cell fates during development. In addition, BRM is required for transcriptional activation of many genes on polytene chromosomes, and both PBAP and BAP localize to hyperacetylated regions on polytene chromosomes, emphasizing their general role in transcriptional activation.

In mammalian cells, BAF is required for the function of many transcriptional activators such as glucocorticoid receptor, estrogen receptor, retinoid receptor, C/EBP β , c-Myc, heat shock factor, and MyoD. Mice homozygous for mutation in either BRG1 or mSNF5/INI1, genes encoding subunits of SWI/SNF, die in early development prior to implantation. Mice heterozygous for the same mutations confer susceptibility to many tumor types, including glandular epithelial tumors and malignant rhabdoid tumors. Mutations in human SNF5/INI1 are causative for an aggressive, pediatric rhabdoid tumor as well as other types of neoplasms, highlighting the role of SWI/SNF as a tumor suppressor. In addition, the SWI/SNF subunit BAF250a is essential for pluripotency and self-renewal

in mouse embryonic stem cells (ESCs), while human SWI/SNF is involved in Myo-D-mediated muscle differentiation. Thus, SWI/SNF-mediated chromatin remodeling is important for gene expression, development, cell-cycle control, stem-cell maintenance, and differentiation.

In addition to its roles in transcription, the yeast SWI/SNF complex also facilitates the repair of DNA double-strand breaks within a condensed, heterochromatin context. *In vitro* data indicate that SWI/SNF action can evict the Sir3 heterochromatin protein from nucleosomal arrays, promoting formation of an early intermediate in homologous recombination. On the contrary, chromatosomes pose a different challenge. H1 linker histone inhibits remodeling by SWI/SNF and many other remodeling enzymes, and this inhibition can be relieved by H1 phosphorylation. More recently, work from the Becker group has shown that some ATP-dependent remodeling enzymes are proficient at remodeling chromatin that contains linker histones.

SWI/SNF has a single bromodomain within the Swi2/Snf2 ATPase subunit, which is important for localization of SWI/SNF to several genes. Consistent with this, histone acetylation by the Spt-Ada-Gcn5-acetyltransferase and NuA4 acetyltransferase was found to stabilize interaction between SWI/SNF and nucleosomes in a manner dependent on the Swi2/Snf2 bromodomain. RSC has multiple bromodomains, located on several subunits, and their collective affinity for multiple-acetylated histone moieties may aid the targeting/recruitment of RSC to genomic loci. Interestingly, electromagnetic (EM) imaging suggests that RSC displays different conformations in response to acetylated peptides (H3K9Ac and H3K14Ac), and thus acetylated nucleosomes may alter its structure/activity via its interaction with multiple bromodomains.

CHD/Mi-2 Family

The CHD family of ATPases contains the DExx-HELICc ATPase domain with a short insertion, and a tandem chromodomain that recognizes methylated lysines. There are two classes: monomeric CHD remodelers (in yeast and higher eukaryotes) and Mi-2/NuRD remodelers in a multi-protein complex (only in higher eukaryotes). Recruitment of human CHD1 may be aided by interaction between its tandem chromodomains and the active histone mark, H3K4me. Alternatively, the chromodomains in Mi-2 are hypothesized to bind DNA rather than methylated lysine, as a mutation in its chromodomain eliminates binding and remodeling of unmodified nucleosomes.

CHD remodeling enzymes have multiple functions. CHD1 acts as a monomer to slide and eject nucleosomes to promote transcription. Specifically, *drosophila* CHD1 (dCHD1) colocalizes with elongating RNAPII, as does yeast CHD1, which also physically interacts with elongation factors. In contrast, the multi-subunit complex Mi-2/NuRD, which contains an HDAC and methyl CpG-binding domain proteins, represses transcription. Moreover, dCHD1 can function in concert with the histone chaperone Nap1 to assemble chromatin *in vitro*. *In vivo*, dCHD1 was shown to deposit the histone H3.3 variant in the male pronucleus, further confirming its role in chromatin assembly. In yeast, however, CHD1 inhibits DNA replication, and thus the role of CHD1 may be tailored to different biological

contexts. Mice lacking CHD4/Mi-2 β , although viable, display hematopoietic and immune defects. CHD7 mutation in mice causes CHARGE syndrome, the genetic disorder associated with growth retardation, heart defects and deafness. Mice with a CHD8 mutation are not viable. Furthermore, CHD5 has been implicated as a tumor suppressor that activates expression of p16 and p19 associated with neuroblastoma in human.

ISWI Family

The ISWI family of remodeling enzymes (NURF, ACF, and CHRAC) contain the DExx-HELICc ATPase domain with a short insertion, and a SANT-SLIDE domain that serves as a nucleosome-recognition motif that binds to unmodified histone tails and DNA. A role for ISWI in general is to provide regular spacing of nucleosomes after transcription and DNA replication, the result of which is associated with a closed chromatin state. Recent studies suggest that ACF may act as a dimer to provide even spacing of nucleosomes. EM imaging suggests that two SNF2 molecules may associate with a single nucleosome, and it is hypothesized that the back-and-forth movement of the nucleosome from either direction may allow proper sensing of the length of linker DNA. In yeast, it was shown that ISWI (Isw2) increases nucleosome occupancy over intergenic regions to prevent inappropriate transcription initiation from cryptic sites. Moreover, ISWI can contribute to the eviction of TATA-binding protein (TBP) to prevent transcription initiation. However, another member of ISWI in higher eukaryotes, NURF, can disrupt nucleosomes to promote RNAPII activation. Notably, dNURF is a member of the Trithorax group that activates the expression of *HOX* genes during development in flies.

INO80 Family

The INO80 (inositol requiring 80) family of remodeling enzymes is different from other enzymes in many respects. First, they contain multiple ATPases. In addition to one large ATPase subunit (Ino80), there are two other AAA⁺ ATPases called Rvb1 and Rvb2, which form hetero-dodecamers. Second, the ATPase domain has a long insertion between the DExx and HELICc domains, which serves as a platform for binding Rvb1–Rvb2. Third, one member of this family, SWR1, can restructure nucleosomes by mediating the exchange of a nucleosomal H2A–H2B dimer for an H2A.Z–H2B dimer. In yeast, the Ino80 and Swr1 complexes are the two members of this class of remodeling enzymes.

Swr1 remodeling enzymes deposit H2A.Z–H2B dimers in a replication-independent manner at nucleosomes flanking the transcription start site (Figure 2). When present with H3.3 (the only H3 isoform in yeast), the H2A.Z-containing nucleosomes are thought to be less stable and more prone to disruption (see above), which may aid in transcriptional activation. At the sites of a DSB, Swr1 (together with NuA4 acetyltransferase) exchanges phosphorylated H2A.X (γ -H2A.X) with H2A.Z, which is believed to facilitate movement of nucleosomes during recombinational repair. To date, only the Swr1 complex has displayed dimer exchange activity, and it lacks other activities that could mobilize nucleosomes (e.g., sliding

or eviction). Thus, the Swr1 complex seems to be specialized for restructuring nucleosomes.

The Ino80 complex was first identified in a genetic screen for mutants defective in the transcriptional response to inositol depletion. The Ino80 complex is now known to control transcription of a subset of yeast genes, and to regulate efficient DNA double strand break repair, stabilize stalled replication forks, and promote sister chromatid cohesion. Thus, Ino80 plays a broad role in chromatin metabolism. The Ino80 complex contains 15 subunits, and the ATP-dependent nucleosome-sliding activity of Ino80 is hypothesized to be important for transcriptional activation. Like the Swr1 complex, the Ino80 complex is recruited to DSB chromatin in a manner dependent on phosphorylated H2A.X. Genetic evidence has led to a model in which the Ino80 complex might reverse the action of the Swr1 complex by exchanging H2A.Z–H2B dimers with H2A–H2B, hence restoring the chromatin state that was present prior to DSB formation. This restoration process appears to be important for eliminating the cell-cycle checkpoint response when cells encounter an unreparable DSB.

The INO80 family of remodeling enzymes is conserved in higher eukaryotes. In *Drosophila*, Pho-dINO80 and Tip60 complexes share similarities with yeast Ino80 and Swr1 complexes, respectively. In mammals, there are INO80, SRCAP, and TRRAP/Tip60 complexes. Notably, the mammalian Tip60–p400, which encodes an acetyltransferase, plays an important role in ESCs. A set of genes in the ESC contains bivalent nucleosomes that are decorated with both activating and repressive histone modifications (H3K4me3 and H3K27me3), and it is thought that this binary state allows genes to be poised for activation. Consistent with this notion, many of these genes are preferentially activated during ESC differentiation. It was recently demonstrated that Tip60–p400 localizes to, and acetylates the bivalent nucleosomes, which may be important for stem-cell maintenance. Similarly, H2A.Z, which is incorporated into chromatin by the SWR1 family member, was shown to localize to promoters of developmentally important genes in ESC. In lineage-committed cells, H2A.Z redistributes to a different set of genes, suggesting that H2A.Z is important for regulating gene expression during differentiation.

Figure 2 Swr1-dependent deposition of H2A.Z–H2B dimers into nucleosomes flanking the transcriptional start site. Histone acetylation by NuA4 and interaction with transcriptional activators guide Swr1 to the target loci.

Figure 3 A diagram depicting a current model to explain the mechanism of how ATP-dependent chromatin remodeling enzymes slide a nucleosome translationally. See text for details.

Mechanism of Remodeling

Sliding and eviction of nucleosomes require disruption of 14 histone-DNA contacts. Many previous models have speculated that this disruption is mediated either by a conformational change of the nucleosome, or conversely by a conformational change in the remodeling enzyme. However, the classification of all the ATPases as members of the SF2 family of DEAD/H-box helicases/translocases (they lack a motif that allows separation of a DNA duplex, thus they do not have helicase activity) and the biophysical tests of this by single molecule experiments, led to the current model that remodeling enzymes are DNA translocases that pump DNA around histone octamers.

In a simplified model, the DNA-binding domain of the remodeling enzyme binds linker DNA near the entry-exit site, and the translocase domain binds a fixed place on the octamer, namely two DNA turns from the dyad, which is the central position of the nucleosome. The translocase domain then pumps DNA from this internal location, and generates a DNA loop (of varying sizes for different remodelers) near the dyad. The loop then propagates along the octamers, with the help of DNA-tracking domain of the remodeler, resulting in translational movement of the nucleosome (Figure 3). The directionality of the movement may be determined by the non-ATPase subunits. For example, *drosophila* ISWI enzymes (NURF, CHRAC, and ACF) all share one ATPase subunit ISWI. By itself, ISWI slides the nucleosome from the center to the end of a DNA fragment, while CHRAC (which contains ISWI with three other proteins) repositions the nucleosome from the end to the center of a DNA template. Recently, ACF was hypothesized to work as a dimer to coordinate bidirectional movement, raising the possibility that communication between the remodelers could determine directionality. However, cryo-EM studies indicate one nucleosome per macromolecular remodeling enzyme (e.g., SWI/SNF and RSC), suggesting other mechanisms for directionality.

Summary

Cells are challenged with the conundrum of having to package and safely store long strands of DNA, and at the same time, to

allow regulated usage of the packaged DNA for gene expression, DNA repair, and DNA replication. The dynamic interplay of three mechanisms (1) histone modifications, (2) incorporation of histone variants, and (3) ATP-dependent chromatin remodeling, achieves this feat, and allows cells to coordinate the accessibility of DNA with cellular metabolism and growth. Studies in the past decades have elucidated detailed mechanisms as to how chromatin dynamics is regulated. Notably, the advances of single-molecule studies have led to a new model for how ATP-dependent chromatin remodelers change nucleosomal position. Structural studies of remodeling enzymes have begun to emerge, although insights into how they bind nucleosomes have been difficult to achieve. In addition, most of the *in vitro* work has been done with mononucleosomes or unfolded arrays of nucleosomes, the substrates that do not necessarily reflect chromatin structure *in vivo*. Thus, future work to understand how the histone modifications and histone variants alter the higher-order structure of chromatin, and how ATP-dependent chromatin remodeling enzymes access DNA from folded and more condensed form of chromatin, is anticipated.

Glossary

Autophagy From the Greek, *auto* oneself, *phagy* to eat; an intracellular process involving the degradation of organelles and/or proteins through the formation of vesicles that subsequently fuse with lysosomes.

Coactivator A protein that interacts with DNA-binding factors to stimulate gene transcription. Coactivators interact with and stabilize the transcriptional initiation complex, which contains RNA polymerase II and associated factors. In addition, coactivators have histone acetyltransferase activity, which is required for the polymerase to access DNA within chromatin and transcribe it into RNA.

Hypoxia response elements (HREs) These are defined functionally as *cis*-acting DNA sequences that are sufficient,

when inserted into heterologous reporter gene (encoding, e.g., firefly luciferase), to mediate hypoxia-inducible transcription of the reporter gene in a hypoxia-inducible factor 1 (HIF-1)-dependent manner.

Micro-RNA (miR) Double-stranded RNA molecules of 21–23 bp that bind to nucleotide sequences with imperfect complementarity located in the 3'-untranslated regions of mRNAs. The binding of an miR to messenger RNA (mRNA) can either block translation of the mRNA into protein or induce degradation of the mRNA.

Mitophagy Some authors use this term to refer to the selective degradation of mitochondria by the process of autophagy.

Hypoxia-Inducible Factor 1 Mediates Transcriptional Responses to Hypoxia in All Metazoan Species

Cells require a constant supply of O₂ for use as the final electron acceptor in the mitochondrial electron transport chain that drives oxidative phosphorylation of adenosine diphosphate to form adenosine triphosphate (ATP). Transfer of electrons from cytochrome *c* oxidase (complex IV) to O₂ results in the formation of H₂O, whereas transfer of electrons from complex I or complex III to O₂ results in the formation of superoxide, which is converted into hydrogen peroxide. Reduced O₂ availability (hypoxia) can lead to cell death due to energy depletion, whereas increased O₂ availability (hyperoxia) can lead to cell death due to excessive production of reactive oxygen species (ROS). Thus, the challenge of oxygen homeostasis is to maintain cellular ATP levels without incurring excess ROS production.

Hypoxia-inducible factor 1 (HIF-1) regulates oxygen homeostasis in all metazoan species that have been analyzed to date, from *Caenorhabditis elegans* to *Homo sapiens*, by controlling many critical adaptive cellular and systemic responses to hypoxia, such as energy metabolism, erythropoiesis, and vascularization. In mammals, HIF-1 is required for proper embryonic development. It has also been shown to play key roles in the pathogenesis of common human diseases, including cancer, chronic lung disease, diabetes, heart failure, infectious and inflammatory diseases, ischemic heart disease, obstructive sleep apnea, ocular neovascularization, peripheral arterial disease, renal failure, rheumatoid arthritis, and stroke.

This article focuses on three aspects of HIF-1 biology and chemistry. First, the molecular mechanisms by which HIF-1 regulates gene transcription are discussed. Second, the wide variety of signal transduction pathways that regulate HIF-1 α protein levels and activity is reviewed. Finally, target genes activated by HIF-1 that maintain oxygen homeostasis by modulating the balance between oxidative and glycolytic metabolism in response to changes in cellular oxygenation are presented.

HIF-1 Functions Principally as a DNA-Binding Protein That Activates Gene Transcription

HIF-1 mediates these physiological effects by functioning as a DNA-binding protein that activates gene transcription. Purification of HIF-1 by DNA affinity chromatography revealed that it was a heterodimer, composed of HIF-1 α and HIF-1 β subunits. Both subunits contain helix-loop-helix (HLH) domain and PER-ARNT-SIM (PAS) homology domain (Figure 1) that mediate dimerization, which is required to juxtapose the basic domains that mediate DNA binding. HIF-1 binds to target genes at hypoxia response elements (HREs), which contain the core sequence 5'-(A/G)CGTG-3'. The first HRE was discovered in the 3'-flanking region of the *EPO* gene, which encodes erythropoietin, the hormone that controls red blood cell production. Subsequently, HREs were identified in 5'-flanking regions and intervening sequences of other HIF-1 target genes.

The binding of HIF-1 results in the recruitment of coactivator proteins, such as CREB binding (CBP) and p300, which is mediated by two transactivation domains (TADs) located in the carboxy-terminal half of HIF-1 α (TAD-N and TAD-C; see Figure 1). Approximately 250 direct HIF-1 target genes have been identified using the reporter gene assay described above and, more recently, by combining genome-wide chromatin immunoprecipitation (ChIP) and messenger RNA (mRNA) expression profiling (ChIP-chip) assays.

HIF-1 Triggers a Transcriptional Cascade

Among the direct target genes that are transcriptionally regulated by HIF-1, the most abundant class encodes other transcription factors. When these transcription factors bind to their target genes, a secondary wave of transcriptional responses to hypoxia occurs. When any given cell type is exposed to hypoxia, the transcription of several hundred genes increases and the

Figure 1 Functional domains of HIF-1 α and protein–protein interactions. bHLH, basic helix–loop–helix domain; PAS, PER-ARNT-SIM homology domain; TAD-N, amino-terminal transactivation domain; ODDD, oxygen-dependent degradation domain; TAD-C, carboxyl-terminal transactivation domain; P, prolyl residue; N, asparaginyl residue.

transcription of a similar number of genes decreases. Although both transcriptional activation and repression in response to hypoxia are HIF-1-dependent, only the genes subject to transcriptional activation are direct HIF-1 target genes. The transcriptional repression that is mediated by HIF-1 is indirect. One obvious mechanism involves direct HIF-1 target genes that encode transcriptional repressors. For example, HIF-1 binds directly to the *DEC1* gene. All of the *DEC1* target genes are secondary targets of HIF-1. Included among the targets for repression by *DEC1* is the *PPARG* gene, which encodes the transcription factor peroxisome proliferator-activated receptor gamma 2 (PPAR γ 2) – whose target genes represent tertiary targets of regulation by HIF-1. When indirect (i.e., secondary or higher order) target genes are taken into account, the number of genes regulated by HIF-1 increases from hundreds to thousands.

HIF-1 Regulates Genes Encoding Histone Demethylases

In addition to DNA-binding proteins, a second key group of transcriptional regulatory proteins includes those that modify chromatin. Among these, the histone acetylases/deacetylases and histone methylases/demethylases appear to play particularly important roles. *JMJD1A*, *JMJD2B*, *JMJD2C*, and *JARID1B* are direct HIF-1 target genes that encode histone demethylases, enzymes that remove methyl groups from lysine residues. As in the case of DNA-binding factors that are regulated by HIF-1, the altered expression of histone demethylases is likely to result in altered rates of transcription of dozens or even hundreds of genes in hypoxic cells. Depending on the specific histone and lysine residue involved, such demethylation can either increase or decrease transcription of the gene to which the histones are bound. Specific genes whose transcription is modulated under hypoxic conditions as a result of histone demethylation have not yet been identified. Nevertheless, these findings suggest that HIF-1 plays an important role in altering the epigenetic state of chromatin in response to changes in cellular oxygenation.

HIF-1 Regulates the Transcription of Micro-RNAs

One of the most remarkable recent advances in the field of molecular biology has been the identification of hundreds

of short micro-RNAs (miRNAs) that bind to the 3'-untranslated regions of mRNA molecules and thereby either block their translation into protein or induce their degradation. The expression of a growing number of miRNAs is regulated by hypoxia in an HIF-1-dependent manner via direct binding of HIF-1. By doing so, HIF-1 exerts a tremendous effect not only on mRNA levels but also on protein levels, that is, HIF-1 is an indirect regulator of translation. miRNA-induced mRNA degradation may represent another major mechanism by which HIF-1 can indirectly repress gene expression.

Transcriptional Regulation by HIF-1 α Monomers

All of the mechanisms described above by which gene and protein expression are directly or indirectly regulated involve binding of the HIF-1 α :HIF-1 β heterodimer to DNA. However, HIF-1 α has also been shown to regulate gene expression independently of HIF-1 β . It does so not by binding to DNA but by binding to other transcription factors. Transcription of the *MSH2* and *MSH6* genes, which encode subunits of the mismatch DNA repair protein MUTS α , is activated by promoter binding of SP1, which then recruits MYC. Under hypoxic conditions, HIF-1 α displaces MYC from binding to SP1, thereby blocking transcriptional activation. By binding to SP1 and blocking transcriptional activation, HIF-1 α functions as a co-repressor in this context, which provides another expression of mRNAs that may be reduced in response to hypoxia. Remarkably, HIF-1 α also functions as a co-activator of NOTCH-dependent transcription by direct binding to the NOTCH intracellular domain.

Regulation of HIF-1 α Levels and Transcriptional Activity

Given the complex and wide-ranging effects of HIF-1 α :HIF-1 β heterodimers and HIF-1 α monomers on gene expression, it is perhaps not surprising that HIF-1 α levels and activity are subject to complex and wide-ranging regulatory mechanisms that modulate HIF-1 α mRNA levels, protein synthesis, protein stability, and TAD function.

HIF-1 α mRNA Levels

HIF-1 α mRNA levels increase dramatically in tissues subjected to hypoxia or ischemia *in vivo*. However, because HIF-1 α mRNA levels are only transiently regulated by hypoxia in cultured cells, it has been difficult to study the molecular mechanisms involved. For example, it is not known whether such regulation occurs at the level of HIF-1 α mRNA synthesis or stability.

HIF-1 α Protein Levels

Regulation of HIF-1 α stability by acute hypoxia

HIF-1 α protein levels increase dramatically in tissues subjected to hypoxia or ischemia *in vivo* and in cultured cells subjected to hypoxia. Analysis of cultured cells revealed that proteasomal degradation of HIF-1 α is inhibited under hypoxic conditions. Delineation of the molecular basis for this response revealed a direct mechanism by oxygen modulates HIF-1 α levels. In the presence of adequate O₂ concentrations, HIF-1 α is hydroxylated on two proline residues (Pro402 and Pro564 in human HIF-1 α) by a family of dioxygenases (designated PHD1, PHD2, and PHD3) that utilize HIF-1 α , O₂, and α -ketoglutarate as substrates and generate prolyl-hydroxylated HIF-1 α , succinate, and CO₂ as products. In tissue culture cells, PHD2 is specifically required for maintenance of low HIF-1 α levels under nonhypoxic conditions. The protein OS-9 binds to both HIF-1 α and PHD2, thereby stabilizing complex formation and increasing the efficiency of the hydroxylation reaction. SIAH2 is a ubiquitin ligase that targets PHD1 and PHD3 for degradation. SIAH2 expression is induced by hypoxia, which may further contribute to loss of prolyl hydroxylase activity.

Prolyl hydroxylation of HIF-1 α is required for binding of the von Hippel–Lindau (VHL) protein, which recruits Elongin C and its associated ubiquitin-ligase subunits (Elongin B, RBX1, CUL2, and an E2 ubiquitin-conjugating enzyme). The protein SSAT2 binds to HIF-1 α , VHL, and Elongin C, thereby stabilizing complex formation and increasing the efficiency of the ubiquitination reaction. Polyubiquitination of HIF-1 α targets the protein for degradation by the proteasome. VHL-dependent ubiquitination is counteracted by VHL-deubiquitinating enzyme 2, which is itself a target for VHL-dependent ubiquitination and degradation.

Under hypoxic conditions, the catalytic activity of the prolyl hydroxylases is inhibited, the fraction of HIF-1 α that escapes ubiquitination increases, leading to decreased HIF-1 α degradation and rapid protein accumulation. The precise mechanism by which hypoxia inhibits prolyl hydroxylase activity is somewhat controversial. Under conditions of anoxia or severe hypoxia, the reduced substrate (i.e., O₂) availability is a sufficient explanation for loss of catalytic activity. Under more modest hypoxia that is typically observed under physiological conditions, it is not clear whether O₂ is limiting. Instead, hypoxia-induced ROS generation may lead to inhibition of hydroxylase activity as a result of oxidation of the Fe(II) ion located at the catalytic center of the enzyme. These mechanisms are not mutually exclusive.

Regulation of HIF-2 α stability by acute hypoxia

Based on its sequence similarity to HIF-1 α , a related protein that is designated HIF-2 α was identified by database searches.

HIF-2 α also dimerizes with HIF-1 β and binds to HIF-1 target genes. However, in contrast to HIF-1 α , which is ubiquitously expressed, HIF-2 α is expressed in a limited number of cell types and is only found in vertebrate species, where it appears to play important roles in specialized systems for O₂ delivery such as erythropoiesis. HIF-2 α also contains two proline residues that are hydroxylated by PHDs in well-oxygenated cells, leading to its ubiquitination by the VHL-Elongin C ligase complex, and proteasomal degradation.

Differential regulation of HIF-1 α and HIF-2 α stability by prolonged hypoxia

Kinetic analyses have revealed that HIF-1 α is strongly induced by acute hypoxia, with peak protein levels observed after 4–8 h and declining levels after 16–24 h. In contrast, HIF-2 α levels are induced modestly at 4–8 h and increase progressively at time points >24 h. A potential molecular mechanism underlying the differential effect of prolonged hypoxia is the recent identification of the HSP70–CHIP complex as an E3 ubiquitin ligase that binds to HIF-1 α and catalyzes its ubiquitination, leading to subsequent proteasomal degradation. Although HSP70 also binds to HIF-2 α , it does not efficiently recruit CHIP and, as a result, the HSP70–CHIP complex does not affect the stability of HIF-2 α protein.

Role of HSP90 in stability of HIF-1 α and HIF-2 α

Inhibitors of heat shock protein HSP90 such as 17-allylamino-geldanamycin (17-AAG), which are currently in clinical trials as anti-cancer agents, have been shown to induce the degradation of HIF-1 α and HIF-2 α in an O₂-, PHD-, and VHL-independent manner. 17-AAG blocks the binding of HSP90 to PAS-A subdomain of HIF-1 α , which is instead occupied by RACK1, which recruits Elongin C and its associated ubiquitin ligase complex, leading to HIF-1 α ubiquitination and degradation. Whereas VHL only binds to HIF-1 α and recruits the Elongin C complex in an O₂-dependent manner, RACK1 binding and recruitment of Elongin C complex is 17-AAG dependent but O₂ independent. The protein SSAT1 binds to both HIF-1 α and RACK1, stabilizing complex formation and increasing the efficiency of the ubiquitination reaction. It is remarkable that SSAT1 and SSAT2, which are homologs that share 46% amino acid identity, both bind to and promote the ubiquitination of HIF-1 α , but they do so by completely different mechanisms.

Regulation of HIF-1 α stability by small ubiquitin-related modifier

Conjugation of the 100-amino-acid small ubiquitin-related modifier (SUMO) protein to HIF-1 α promotes the binding of VHL even in the absence of prolyl hydroxylation. Mice that lack SENP1, which is a protease that removes conjugated SUMO from HIF-1 α , die of anemia due to EPO deficiency that results from excessive SUMO-dependent ubiquitination and degradation of HIF-1 α .

Regulation of HIF-1 α protein synthesis

In some normal cell types and many cancer cells, the rate of translation of HIF-1 α mRNA into protein is regulated by the activity of the protein kinase mTOR complex 1 (mTORC1), which activates ribosomal protein S6 kinase and inactivates eukaryotic initiation factor 4E binding protein 1, thereby

promoting the translation of a subset of cellular mRNAs. The effect of mTOR on HIF-1 α synthesis is particularly prominent in cancer cells with somatic mutations, leading to gain of function for activators of mTORC1 (e.g., phosphatidylinositol 3-kinase and AKT) or loss of function for inhibitors of mTORC1 (e.g., LKB1 and the TSC1/TSC2 complex) and such effects are observed under nonhypoxic conditions. In many cancer cells, the synthesis of HIF-1 α protein is dependent upon mTORC1 activation, such that treatment with rapamycin dramatically reduces HIF-1 α protein levels even under hypoxic conditions, providing a second example of an anti-cancer agent that inhibits HIF-1 α expression.

Regulation of HIF-1 α TAD function by hypoxia

Binding of the co-activators CBP and p300 to the TAD of HIF-1 α under nonhypoxic conditions is blocked by the hydroxylation of an asparagine residue (Asn-803 in human HIF-1 α) by another dioxygenase, designated FIH-1 (factor inhibiting HIF-1), which also uses O₂ and α -ketoglutarate as reaction substrates. Thus, both the half-life and transcriptional activity of HIF-1 α are regulated by O₂-dependent hydroxylation reactions. FIH-1 also hydroxylates HIF-2 α but appears to play a less important role in regulation of its target genes. Recently, the protein MINT3 was shown to interact with FIH-1 and block its hydroxylase activity.

Regulation of HIF-2 α TAD function

In tissue culture cells, the binding of HIF-2 α to target genes (as identified by ChIP assays) does not lead to transcriptional activation and evidence suggests the presence of a corepressor that blocks HIF-2 α TAD function. However, the identity of the putative corepressor and its mechanism of action remain unknown.

Regulation of HIF-1 α expression and activity by intermittent hypoxia

In patients with obstructive sleep apnea, pharyngeal soft tissue occludes the airway during sleep, resulting in episodes of apnea (cessation of breathing) that last 15–30 s, leading to hypoxemia (reduced arterial PO₂), which awakens the patient, who clears his/her airway and resumes breathing, then returns to sleep to repeat the cycle of hypoxia and reoxygenation many times over the course of each night. A major consequence of obstructive sleep apnea is systemic hypertension (high blood pressure), which increases the risk of heart attack, heart failure, and stroke. Animal and cell-based models of chronic intermittent hypoxia (CIH) reveal that the induction of HIF-1 α plays a key role in disease pathogenesis. CIH results in the generation by nicotinamide adenine dinucleotide phosphate (NADPH) oxidase of ROS, which activate Ca²⁺ signaling pathways involving: phospholipase C- γ and protein kinase C, which inhibit prolyl hydroxylase activity and induce mTOR activity, thereby markedly increasing HIF-1 α protein levels; and Ca²⁺-calmodulin kinase, which phosphorylates p300, thereby increasing its binding to the HIF-1 α TAD. Remarkably, whereas CIH increases HIF-1 α protein levels by the mechanisms described above, it decreases HIF-2 α levels by inducing calpain-1-dependent degradation of HIF-2 α . Mice that are heterozygous for an HIF-1 α -null allele do not develop CIH-induced hypertension, nor do mice treated with a calpain inhibitor, which also blocks

CIH-induced HIF-2 α degradation. Thus, dysregulation of both HIF-1 α and HIF-2 α is involved in the pathogenesis of CIH-induced hypertension.

Regulation of Energy Metabolism by HIF-1

Given the fact that HIF-1 is present in the simple roundworm *C. elegans*, which consists of only ~1000 cells and contains no specialized systems for O₂ delivery, it appears that the ancestral function of HIF-1 was to optimize O₂ utilization such that ATP generation was not accompanied by excess ROS production. Whereas it was well known that hyperoxia is associated with increased ROS production, recent studies have demonstrated that acute hypoxia leads to increased ROS levels, which are required to inhibit the prolyl hydroxylases that negatively regulate HIF-1. This is a classic stimulus-response pathway because under conditions of prolonged hypoxia, ROS levels actually decrease below those observed under nonhypoxic conditions and this decrease is HIF-1 dependent. In the absence of HIF-1 α , ROS levels remain increased and cause cell death within 72–96 h.

HIF-1 has been shown to mediate several different adaptive responses that lead to reprogramming of cellular energy metabolism. Perhaps the most subtle of these adaptations is a subunit switch in cytochrome *c* oxidase from the COX4-1 to the COX4-2 isoform. HIF-1 directly activates expression of the genes encoding COX4-2 and LON, a mitochondrial protease that is required for the degradation of the COX4-1 subunit. This subunit switch optimizes complex IV activity under hypoxic conditions; that is, it increases the efficiency by which electrons are transferred to O₂ by cytochrome *c* oxidase to form water rather than the premature escape of electrons to form superoxide. Remarkably, yeast also execute a homologous subunit switch but do so by an entirely different molecular mechanism, as they lack HIF-1, suggesting that this is an example of convergent evolution: an important problem was solved independently in two different lineages.

The COX subunit switch is likely to maintain redox homeostasis under conditions of mild hypoxia, whereas more severe hypoxia may require a reduction in the flow of electrons through the respiratory chain. To accomplish this, HIF-1 activates the expression of the *PDK1* gene, which encodes pyruvate dehydrogenase (PDH) kinase 1. PDK1 phosphorylates and inactivates the catalytic subunit of PDH, the enzyme that converts pyruvate to acetyl coenzyme A (CoA) for entry into the tricarboxylic acid (TCA) cycle, which generates reducing equivalents (in the form of nicotinamide adenine dinucleotide (NADH)) that are supplied to the respiratory chain. Forced expression of PDK1 rescues HIF-1 α -null cells by reducing ROS levels under hypoxic conditions.

Coincident with the reduction in oxidative metabolism, HIF-1 increases the expression of glucose transporters and glycolytic enzymes to increase the uptake of glucose and its conversion to lactate. This increased glycolytic flux is necessary because of the greatly reduced efficiency of ATP generation from glycolytic as compared to oxidative metabolism of glucose.

Although PDK1 prevents the formation of acetyl-CoA from pyruvate, mitochondrial fatty acid oxidation also generates

acetyl-CoA. Thus, an even more draconian measure to reduce ROS production is to reduce the mitochondrial mass of the cell. HIF-1 activates expression of the *BNIP3* gene, which encodes a mitochondrial protein that targets mitochondrial-selective autophagy. Forced expression of BNIP3 rescues HIF-1 α -null cells by increasing autophagy and reducing ROS levels under hypoxic conditions.

Most recently, HIF-1 was shown to induce the expression of the miRNA miR-210 that bound to the mRNA encoding iron-sulfur cluster assembly proteins ISCU1/2, which are required for assembly of the TCA cycle enzyme aconitase and complexes I, II, and III of the electron transport chain. This provides yet another mechanism by which HIF-1 can down-regulate mitochondrial metabolism under hypoxic conditions, underscoring the critical nature of this ancestral response to hypoxia.

Glossary

Dark fermentation An anaerobic metabolic process in which sugar substrate, oxidized by bacteria via the glycolytic pathway, forms pyruvate, reductant, and adenosine triphosphate (ATP), from which mixed products, including ethanol, acetate, lactate, hydrogen, etc., can be produced in exothermic reactions.

Microbial electrolysis cell (MEC) An MEC consists of immobilized bacteria on an anode, which oxidize waste organic materials, with energy capture at an anaerobic cathode; a small applied over-potential is required to facilitate H₂ production.

Photofermentation A light-driven metabolic process in which organic acids are converted to hydrogen by photosynthetic bacteria.

Introduction

Hydrogen can be produced from biomass using thermochemical (pyrolysis and gasification), photobiological (photo-fermentation), electrochemical (microbial electrolysis), and dark fermentative approaches. Thermochemical routes represent nearer term and the others, midterm technologies, requiring additional research and development (R&D) and cost-reduction efforts. All of these are termed 'second-generation technologies' and are much more efficient in terms of land utilization than corn ethanol production. This article highlights fermentation approaches with a brief discussion of the enzymes, organisms and metabolic pathways, and processes involved in H₂ production from biomass.

Enzymes

Two types of redox enzymes catalyze biological H₂ production, hydrogenases (H₂ases) and nitrogenases (N₂ases). Hydrogenases are metallo-proteins that catalyze the oxidation or reduction of H₂ according to the following:

Based on the structure of the active site metal center, H₂ases can be classified as two major types, [FeFe]- and [NiFe]-H₂ases (Figure 1). Although unrelated phylogenetically, both contain CN[−] and CO ligands attached to the iron atoms of the binuclear metal center to efficiently catalyze the inter-conversion of H⁺ and H₂.

Nitrogenases catalyze the fixation of atmospheric N₂; come in forms that contain FeMo, FeV, or Fe-only co-factors; and can produce H₂ as a by-product of N₂ fixation, but at a high energy cost.

[FeFe]-Hydrogenases

[FeFe]-hydrogenases are primarily found in anaerobic bacteria and eukarya. The modular structure and domain organization of these H₂ases are diverse from a simple monomer (e.g., H₂ase I from *Clostridium pasteurianum*) to more complex trimers

or tetramers (e.g., nicotinamide adenine dinucleotide (phosphate) (NAD(P)H)-dependent [FeFe]-H₂ases from *Thermotoga maritima* and *Thermoanaerobacter tengcongensis*). [FeFe]-H₂ases are usually involved in H₂ production, but the periplasmic [FeFe]-H₂ase of *Desulfovibrio vulgaris* Hildenborough can function as an uptake hydrogenase. The active site (H-cluster) is composed of a [4Fe-4S] cluster coordinated to a unique binuclear Fe-Fe center via a conserved cysteine residue (Figure 1(a)). Maturation (functional assembly) of [FeFe]-H₂ases require a minimum of three auxiliary proteins, HydE, HydF, and HydG. The HydE and HydG maturases contain the CxxxCxxC motif, the three cysteines of which coordinate a [Fe₄S₄] cluster, and belong to the class of radical S-adenosylmethionine (SAM) enzymes. The HydF is also a metallo-protein with guanosine triphosphatase (GTPase) activity at its N-terminal region and binds a FeS cluster at its C-terminus. HypF alone is considered to be sufficient to deliver the CN[−] and CO ligands for activating the [FeFe]-H₂ase apo-enzyme.

NiFe-Hydrogenases

[NiFe]-hydrogenases are found in many bacteria, cyanobacteria, and archaea, but not in eukaryotes. The core enzyme is a hetero-dimer with the catalytic large subunit (c. 60 kDa) hosting the bimetallic NiFe-active site and the small subunit (c. 30 kDa) hosting the Fe-S clusters. The NiFe-active site is deeply buried within the large subunit and is coordinated to the protein via four conserved cysteines (Figure 1(b)). The small subunit contains up to three accessory Fe-S clusters, which mediate electron transfer from/to the catalytic site to/from the physiological electron mediator. The most common type is the membrane-bound, H₂-uptake, [NiFe]-H₂ase. Its orientation results in a release of protons in the periplasmic compartment that could potentially facilitate energy coupling to H₂ oxidation. The maturation of the catalytic center within the large subunit is based on the model developed in *Escherichia coli*. It is under the control of six genes in the *hyp* operon as well as an endopeptidase. The biosynthetic pathways for the CN[−] and CO ligands are different. The cyanide ligand derived from carbamoylphosphate (CP) is inserted via HypE and HypF, and the CO ligand may be synthesized from acetate or one of its precursors. HypC and HypD are involved in Fe

Figure 1 Active site of (a) [FeFe]-hydrogenases and (b) [NiFe]-hydrogenases.

coordination, and HypA, HypB, and SlyD are responsible for nickel delivery in a GTP-dependent reaction. The last step is a proteolytic cleavage of the carboxyl terminus following Ni insertion.

Nitrogenases

In addition to H_2 ase, H_2 can also be produced by N_2 ase, a metallo-enzyme with the most common type harboring a molybdenum and iron metal cluster. Nitrogenase is de-repressed when the growth medium is limited in ammonium. It normally functions in converting atmospheric N_2 into ammonia, a nutrient supporting cell growth according to the following:

One notable feature common to all N_2 ases is the obligatory production of H_2 as a by-product. In the absence of N_2 , H_2 is produced as the sole by-product but consumes 4 mol of adenosine triphosphate (ATP) in the process according to

Consequently, N_2 ase-mediated H_2 production should and does proceed in an inert atmosphere (argon gas) devoid of N_2 to improve overall conversion efficiency. Nitrogenase contains two subcomponents, the MoFe-protein and the Fe-protein. MoFe-protein harbors the MoFe-metallo-cluster catalytic center where N_2 and proton reduction take place. The Fe-protein contains a single $[4Fe4S]$ cluster as well as an Mg-ATP-binding site for electron transfer and ATP hydrolysis. The requirement for large amounts of ATP (contrary to H_2 ases) to drive the uphill reaction, thus, decreases the overall efficiency of H_2 production. Another drawback of N_2 ases is its low turnover rate compared to H_2 ases. Yet, the large negative free-energy change ($\Delta G'^0 = -463 \text{ kJ mol}^{-1}$) accounts for its spontaneous and irreversible nature in H_2 production when compared to H_2 ase. Nitrogenase is present in almost all purple nonsulfur photosynthetic bacteria (PSB) (see section Photofermentation). These organisms, therefore, are ideal candidates

to convert waste organic acids (fermentation waste) to H_2 in the light (photofermentation).

Substrates

Biomass is a broad term including organic materials produced by living organisms or found in waste streams. Lignocellulosic biomass is comprised of cellulose (pure glucose polymer) as the main constituent along with lignin and hemicelluloses (mostly pentose sugars). Cellulose is the most abundant biopolymer on Earth, yet at present only about 4% of US energy comes from biomass. Most common forms of biomass are the wood and its waste, agricultural residues, and municipal solid waste (MSW). A few biomass sources are cultivated as energy crops such as switch grass, miscanthus, and poplar due to their fast growth rates, low water usage, and minimal nutrient requirements. In recent years, carbohydrate- and organic acid-enriched wastewater from various industries (e.g., cattle farm, food processing, dairy processing, molasses based, and starch hydrolysate) has also attracted attention as potential substrate for biofuel production in combination with waste reduction and water treatment. Utilization of all types of waste biomass will inevitably grow in the coming decades for the production of H_2 , methane, ethanol, and biodiesel.

Due to recalcitrance, lignocellulosic biomass has to undergo pretreatment prior to fermentation. Pretreatment can be carried out by several methods such as steam explosion, ammonia fiber explosion (AFEX), and chemical (acid or base) processing. Pretreatment breaks open the cell walls, producing two main fractions: a soluble fraction containing hemicelluloses and acid-soluble lignin, and a solid fraction containing lignin and cellulose (i.e., lignocellulose). Microbes are readily available to ferment lignocellulose or hemicellulose directly without subjecting either substrate to further enzymatic hydrolysis. The concept of 'consolidated bioprocessing', combining substrate hydrolysis with fermentation in one step, is an attractive and viable option to improve the overall techno-economic feasibility of fermentative H_2 production.

Organisms and Pathways

Dark Fermentation

Many anaerobic microbes including *Clostridia* and *Enterobacter* can carry out dark fermentation reactions, which convert various substrates such as sugars, amino acids, and fatty acids to H_2 , CO_2 , ethanol, and other reduced end products. *Enterobacter aerogenes* is capable of producing H_2 but uses costly glucose and sucrose as the substrates. Of particular interest are the clostridial microbes, many of which are cellulolytic and capable of metabolizing crystalline cellulose. This is accomplished by the assembly of an extracellular cellulosome system, consisting of about 30 catalytic subunits along with noncatalytic subunits for cellulose binding. Cellulosome sizes range from 650 kDa up to 100 MDa, with the latter aggregated as polycellulosomes. Among the clostridial microbes, the thermophilic *Clostridium thermocellum* has the highest reported rate of cellulose degradation. Yet, in general, the clostridial microbes are not genetically tractable, making it difficult for

metabolic pathway engineering. Apart from the *Clostridia*, several other mesophilic anaerobic bacteria such as *Acetivibrio cellulolyticus*, *Bacteroides cellulosolvens*, and many microbes isolated from rumen fluids have the cellulosomes. The list is expected to grow rapidly as more cellulosome-producing microbes are discovered with immense potential for biotechnological applications

Most clostridial microbes use the Embden–Meyerhof (glycolytic) pathway for sugar metabolism (Figure 2). The oxidation of pyruvate to acetyl-CoA via the pyruvate:ferredoxin oxidoreductase (step 3 in Figure 2) results in the concomitant production of H_2 using ferredoxin as the electron donor coupling to a FeFe- H_2 ase (step 4). The NADH generated during glycolysis can also couple directly to a different H_2 ase (step 6) or indirectly via ferredoxin (step 5) to catalyze H_2 production. Hydrogenase is presumed to help dissipate excess energy to maintain redox homeostasis in the organism, which may account for the presence of H_2 ase of different types (FeFe- and NiFe-) in a single organism as has been reported in various *Clostridia*, *Thermoanaerobacter*, and *Thermotoga*. Moreover, fermentative microbes must also rely on other pathways to regenerate $(NAD(P)^+)$, such as those NAD(P)H-consuming reactions that yield lactic and butyric acids, and ethanol as the more reduced end products. This mode of mixed-acid fermentation improves substrate utilization and cell growth, yet it compromises the molar yield of H_2 (mol H_2 /mol hexose). This explains the observed H_2 molar yield of between one and two by most laboratories, even though theoretically a maximal yield of four can be realized when acetate is the sole fermentation end product. Numerous strategies have been proposed to overcome this barrier, and some will be discussed later.

Photofermentation

Noxygenic, purple, nonsulfur PSB have attracted industrial interest for H_2 production from biomass because their

Figure 2 Embden–Meyerhof pathway in *C. thermocellum*. 1. Lactate dehydrogenase, 2. pyruvate:formate lyase, 3. pyruvate:ferredoxin oxidoreductase, 4. Fe–Fe-hydrogenase, 5. NADH:ferredoxin oxidoreductase, 6. NADH NiFe hydrogenase, 7. acetaldehyde dehydrogenase, 8. alcohol dehydrogenase, 9. acetate thiokinase, 10. phosphotransacetylase, 11. acetate kinase.

photosynthetic pathway does not produce O_2 , an inhibitor of both H_2 ase and N_2 ase function. The best-studied PSB belongs to the family of *Rhodospirillaceae* with photosynthetic antenna pigments absorbing light from 400 to 600 nm and from 800 to about 1000 nm. Harnessing only a type II photosystem, *Rhodospirillaceae* must rely on the presence of organic acids (vs. H_2O for oxygenic photosynthetic organisms) as the source of electrons for CO_2 fixation and for proton reduction. *Rhodospirillaceae* are known to utilize a diverse array of organic acids to support photosynthetic growth, with acetic, lactic, formic acids, propionic, and butyric acids being the most common. These compounds are typical waste by-products of dark fermentation. Most, if not all, PSB contain the nitrogenase enzyme, which under certain conditions can be directed solely toward H_2 production, with electrons derived from the oxidation of these organic acids, and ATP generated during the photosynthetic electron transport process. PSB, therefore, can work synergistically when integrated with a dark fermentation system (the latter supplies the required carbon substrates). This integration has dual benefits of addressing waste remediation from dark fermentation, while improving the overall H_2 molar yield.

Processes, Challenges, and Approaches

To improve the techno-economic feasibility of biological H_2 production on a commercial scale, many challenges need to be overcome. The first challenge is the cost of feedstock. Identifying a feedstock that can be easily cultivated, collected, and fermented has been the goal of many studies. Glucose and xylose are ideal substrates, yet they are prohibitively expensive on a commercial scale, because of the energy-extensive pretreatment required to release these simple sugars from complex lignocellulosic biomass. Consolidated bioprocessing using cellulolytic microbes is one of the most promising solutions, because it combines enzyme production, hydrolysis, and fermentation of complex lignocellulosic substrates in a single step.

The second challenge of fermentation is the low H_2 molar yield. Optimization of culture conditions, species selection, biomass retention, and metabolic engineering are all strategies used to increase the H_2 molar yield. Choosing an appropriate microorganism or consortium is key to efficient substrate degradation. Some extremophiles, for example, are capable of fermenting lignocellulosic materials at very high temperatures and are among the most efficient H_2 -producing organisms. An additional benefit to working at high temperature is to prevent contamination by other more ubiquitous, mesophilic methane-producing bacteria. The purpose of biomass retention is to increase cell density within the bioreactor, thereby increasing the rate of substrate conversion and H_2 production. Typical bioreactor configurations used to maintain high cell density include fed batch, immobilized cell membrane recycle, and various filtration device approaches. Metabolic engineering aims at blocking one or more of the competing pathways, thereby redirecting the reaction from formic, lactic, and butyric acid toward acetate production (this could potentially increase the molar yield of H_2 from 2 to 4 mol H_2 mol $^{-1}$ hexose).

The third challenge of fermentative H_2 production is the accumulation of waste organic acids (acetic, formic, lactic,

Figure 3 Process flow diagram of an integrated H₂ production process starting from lignocellulosic biomass.

butyric, etc.). The presence of waste acids not only lowers H₂ molar yields but also requires further treatment. These organic acids can be used as substrates for two other H₂ production processes. **Figure 3** illustrates an integrated, H₂ production process where lignocellulose is first converted to H₂ via dark fermentation, and the resultant organic acids are then converted to H₂ either in a microbial electrolysis cell (MEC) or by photofermentation. MECs recruit immobilized bacteria on an anode to oxidize the waste acids, with energy capture at an anaerobic cathode; a small applied over-potential is required to facilitate H₂ production. In one fermentation–MEC integrated system, the MEC was capable of removing 70–85% of the organic acids from cellobiose fermentation with a system H₂ molar yield near 9.95, the highest reported thus far. The second option is to integrate dark fermentation with photofermentation, in which the purple, nonsulfur PSB can photo-assimilate the waste acids and produce additional H₂. In this case, the highest reported combined molar yield is 7.1 mol H₂ mol^{−1} per glucose. In general, effluents derived from carbohydrate-fed (vs. protein-enriched) fermentation are more suitable for photofermentation due to lower carry-over ammonia concentration, an inhibitor of the nitrogenase function. However, the cost and durability of photobioreactors must be considered to ensure economical feasibility.

Epilog

Future studies will improve both productivity and cost issues by focusing on integrated processes that combine the use of cellulosic biomass rather than starch or simple sugars, dark fermentation using thermophilic bacteria (they exhibit faster rates of H₂ production), and either a photofermentation or an MEC to produce more H₂ (up to 4 mol H₂ mol^{−1} acetate

equivalent) from the organic acid products of the dark fermentation. At the moment, the highest reported molar yield of any integrated system is around 10 mol H₂ mol^{−1} hexose starting from cellobiose fermentation and converting 70–85% of the resulting organic acids to H₂ using an MEC.

Glossary

AP endonuclease An enzyme that makes incisions in DNA on the 5' side of either apurinic or apyrimidinic sites.

Deamination Hydrolytic replacement of an amino group (–NH₂) from a chemical compound with a hydroxyl group.

Dominant negative mutation A mutation that results in a protein that is inactive and, in addition, competes with an active form of the same protein.

Glycosylase (glycosidase) A hydrolytic enzyme that cleaves the bond between a sugar molecule and a nucleic acid base such as thymine.

Monomeric enzyme An enzyme composed of a single polypeptide.

Type II restriction endonuclease An enzyme that cuts both DNA strands at defined positions close to or within a specific base sequence.

5-Methylcytosine (5meC) is found at specific sites in the DNA of *Escherichia coli* and related bacteria, and also in eukaryotes, where it functions in the regulation of gene expression. Hydrolytic deamination of 5meC produces thymine (T) (Figure 1), which is mispaired with guanine (G) in the sister DNA strand. In *E. coli*, the very-short patch (VSP) repair system replaces the mismatched T with cytosine (C), thus preventing the occurrence of a C:G to T:A mutation during the next replication of the DNA (Figure 2). In the absence of VSP repair, spontaneous mutation at the sites of 5meC increases manyfold. VSP repair requires the specific endonuclease Vsr and also a DNA polymerase, pol I, and DNA ligase. MutS and MutL, proteins that are essential for the correction of mispairs arising during DNA replication, are required for efficient VSP repair. In mammals, 5meC occurs in CpG sequences. At least two different enzymes appear to preferentially excise T in a T:G mispair that arises in this context.

VSP Repair in *E. coli*

Discovery of VSP Repair in *E. coli*

Before the advent of DNA sequencing, the relative locations of different mutation sites on chromosomes were determined by performing crosses of different mutants and determining the frequency of wild-type recombinants. The frequency of recombination that requires DNA breakage generally is directly proportional to the distance between mutation sites on the parental genomes. Certain mutations (or markers) appear to recombine with other mutations in their vicinity more frequently than expected. This 'marker effect', which has also been referred to as 'high negative interference', was studied using bacteriophage lambda mutants. The markers in lambda (and in *E. coli*) that display unusually high frequencies of recombination were found to be mutations of 5meC to T. These mutations can be corrected by VSP repair in DNA heteroduplexes during recombination.

Structure and Regulation of *vsr*

A small gene, *vsr*, coding for only 156 amino acids is present in *E. coli* and related enteric bacteria, and is required for VSP repair. It is located adjacent to *dcm*, whose product adds a methyl group to the second cytosine in a 5' CC (A or T) GG sequence (Figure 2). The first seven codons of *vsr* overlap the 3' end of *dcm* and both genes are transcribed from a single promoter. Although their gene transcripts are present on the same messenger RNA, Dcm and Vsr proteins are expressed independently. In actively growing cultures, little Vsr is present in the bacteria, and mutation hot spots are found at the sites of 5meC. In nondividing bacteria, the concentration of Vsr increases significantly and, although deamination of 5meC continues at a rate that is time and temperature dependent, mutations do not accumulate at 5meC. As the bacteria are expected to divide infrequently under natural conditions, VSP repair is an efficient mechanism to prevent mutation at 5meC.

Biochemistry of Vsr

Vsr endonuclease is a monomeric protein whose overall structure and active site have similarities to type II restriction endonucleases. Vsr binds to DNA containing a T:G mispair resulting from the deamination of 5meC (Figure 2). It also binds, with lower affinity, to related sequences lacking the 5'C or the 3'G of the cognate sequence. Binding occurs in the presence of either magnesium or calcium ions, but cleavage occurs only in the presence of magnesium ion. Crystallographic studies have shown that Vsr spreads apart the DNA strands at the mispair site by inserting amino acid side chains, causing the DNA to bend. *In vitro* absence of 5meC from the strand opposite the mispaired T reduces both the rate of DNA binding and the efficiency of enzyme action. This effect has not been observed *in vivo*, where additional factors influence VSP repair.

In vitro studies show that Vsr nicks DNA 5' to the mismatched T. When large amounts of Vsr are present, the

endonuclease activity does not require an additional protein. However, in replicating bacteria, VSP repair activity is enhanced significantly by MutS and MutL. Since the absence of either protein, or of both, has the same effect, it is likely that these products act cooperatively, as they are known to cooperate in mismatch correction of replication errors (MMRs). MutS binds to T:G mispairs in any sequence context and recruits MutL resulting in a MutL–MutS complex that interacts with an endonuclease called MutH. Dominant negative mutations in MutS that block MMR also prevent VSP repair. Studies with purified proteins show that DNA cleavage by Vsr is stimulated by the presence of both MutS and MutL. This suggests that the MutL–MutS complex interacts similarly with both the Vsr and MutH endonucleases.

In addition to Vsr, VSP repair requires DNA polymerase I (Pol I), which has an intrinsic 5′–3′ exonuclease activity that digests away a small number of nucleotides starting at the nick immediately upstream of T. It simultaneously resynthesizes DNA in the 5′–3′ direction. As Pol I is a high-fidelity polymerase, it inserts a C in place of the T that it has removed from the mismatch. The actual number of bases removed is known

to be less than 10, and is perhaps as few as 1 or 2. This is why this repair is referred to as VSP. The repair is completed by DNA ligase, an enzyme that seals single-strand nicks in double-stranded DNA.

Mutagenesis by Vsr

Overproduction of Vsr increases the frequency of mutation at many sites in *E. coli*, mimicking the effect of mutations in *mutS* or *mutL*. Mutagenesis by Vsr can be attributed to its competition for a component of the MMR system. Vsr has been shown to interact with an amino terminal domain of MutL that also interacts with MutH. Thus, it is likely that the concentration of Vsr is maintained at a low level in dividing bacteria to prevent it from competing with MutH for binding to MutL. Vsr would also have a mutagenic effect if it corrected to C:G, a T:G mispair in which the G was a replication error in a newly synthesized strand. It should be noted that MutS has a higher affinity for T:G than for any other mispair. Therefore, it is not surprising that excess MutS reduces VSP repair by competing with Vsr for binding at T:G mispairs that result from deamination of 5meC.

Figure 1 Chemical structures of cytosine and cytosine derivatives. 3,*N*(4) ethenocytosine is a mutagen produced in DNA by endogenous products of lipid peroxidation and by industrial pollutants such as vinyl chloride.

Methyl-CpG-Binding Domain 4 Protein in Eukaryotes

Structure and Biochemistry of Methyl-CpG-Binding Domain 4

The gene for methyl-CpG-binding domain 4 (MBD4) was identified in a search of the human sequence database for a methyl-CpG-binding domain. Mbd4 genes in both the human and mouse code for a ~580 amino acid protein with a methyl-CpG-binding domain near the amino-terminal end and a carboxy-terminal glycosylase domain. The glycosylase region of the protein is related to bacterial glycosylases such as MutY. The enzyme has no lyase activity, so that the removal of the mismatched base leaves behind an abasic site. The sugar-phosphate backbone of DNA can subsequently be cleaved by the human AP endonuclease HAP1, but other endonucleases may also perform this function. There is evidence suggesting that processing of the abasic site also involves interaction with MLH1, a homolog of bacterial MutL.

Specificity

Investigations with human MBD4 have shown that only T:G and U:G mispairs are good substrates for the enzyme.

Figure 2 The life cycle of a dcm site in *E. coli*.

The human MBD4 enzyme binds preferentially to T:G mismatches in the meCpG/TpG context. However, removal of the mismatched base was also observed when U:G and T:G mismatches were in a nonmethylated substrate. T:G mismatches in other contexts are processed at a greatly reduced rate. The fact that U is removed from a mispair with G more rapidly than T suggests that removal of T resulting from deamination of meC may not be the primary function of MBD4.

Cancer Prevention

In the cells of the intestinal mucosa of mice containing inactive *Mbd4* genes there was a two- to threefold increase in C to T mutations in CpG sequences. In combination with mutations in the adenomatosis polyposis (*Apc*) genes, MBD4 inactivation increased the number of tumors and tumor progression. A 3.3-fold increase of C to T mutations at 5meC was also observed in the liver and spleen of mice lacking MBD4. Therefore, it is clear that MBD4 is a significant factor in the prevention of mutations leading to cancer.

Thymine-DNA Glycosylase

Discovery and Specificity of Thymine-DNA Glycosylase

Thymine-DNA glycosylase (TDG) was first isolated during the search for a Vsr-like activity in extracts of human cells. The enzyme has a higher affinity for U:G mispairs than for T:G, and also has significant affinity for 3,*N*⁴-ethenocytosine (Figure 1) paired with G. TDG has a strong preference for mispairs arising in the CpG context. However, there is as yet no direct evidence that it has an important role in preventing mutation resulting from deamination of 5meC.

Biochemistry of TDG

TDG has homologs in other eukaryotes, and also in *E. coli*. It has no apparent amino acid similarity to MBD4 or Vsr.

The enzyme is characterized by low abundance and slow action. TDG can remove from DNA the bases T or U that arise by deamination of 5meC or C, and are, thus, mispaired with G. It also excises 3,*N*⁴-ethenocytosine from DNA. Following removal of T or U from the DNA backbone, TDG remains bound to the newly created abasic site. Studies of human TDG *in vitro* have indicated that an apurinic exonuclease (HAP1) helps TDG turnover and cleaves the abasic sugar phosphate. Repair of the resulting nick in the DNA strand requires both a DNA polymerase and DNA ligase.

Glossary

Cytochromes Redox proteins with an iron-containing porphyrin ring (heme).

Electrochemical proton gradient It defines the membrane-energized state in terms of electrical units.

Genetic regulatory element A molecule that regulates gene expression by interacting with DNA.

Phototroph An organism that converts radiant energy into chemical energy.

Proton motive force An energized state of the membrane resulting from the separation of charges across the membrane.

Respiration The process in which a compound is biologically oxidized by an electron acceptor (O_2 or an O_2 substitute) linked to generation of a proton motive force.

Anoxygenic Phototrophs

On a phylogenetic basis (16S rRNA analyses) phototrophic bacteria and their relatives are grouped in a class, the Proteobacteria, which is formed by several subclasses, named α , β , γ , δ , and ϵ . Facultative photosynthetic bacteria belong to α and β subclasses, for example, genera *Rhodobacter*, *Rhodospirillum*, *Rhodocyclus*, *Rubrivivax*, and *Erythrobacter*.

Metabolic Aspects of Facultative Anoxygenic Bacteria

Facultative phototrophs are probably the most metabolically flexible organisms of the microbial world. Species such as *Rhodobacter* (*Rba.*) *capsulatus* and *Rba. sphaeroides* can grow not only by aerobic respiration and photosynthesis using either organic or inorganic substrates but also by anaerobic respiration with trimethylamine-N-oxide (TMAO) or dimethyl sulfoxide (DMSO) as electron acceptors. Further, some strains of the species *Rhodopseudomonas* (*Rps.*) *palustris*, *Roseobacter* (*Rsb.*) *denitrificans*, and *Rba. sphaeroides* can respire nitrate (NO_3^-) reducing it into dinitrogen (N_2) via nitrite (NO_2^-), and, in some cases, also nitric oxide (NO) and nitrous oxide (N_2O). These energy-generating processes are catalyzed by oxido-reduction protein complexes forming composite electron transport chains. Apparently, not all the above summarized metabolic options are activated or can be available simultaneously in a single species; however, cells of *Rba. capsulatus* or *Rba. sphaeroides* grown photosynthetically in the presence of low oxygen tension (<1%) contain both photosynthetic and respiratory apparatuses.

Electron Transport Chains

Respiration in facultative phototrophs involves numerous redox carriers, namely: (1) transmembrane protein complexes such as nicotinamide adenine dinucleotide (reduced form) (NADH)- and succinate-quinone oxidoreductases (NQR and SQR, respectively), cytochrome (cyt) bc_1 or hydroquinone-cytochrome c oxidoreductase (QCR), quinol oxidase(s)

(QOX), and cyt cbb_3 and/or aa_3 oxidases (COX); (2) electron and/or proton carriers such as ubiquinones (UQ), cyt c_2 , HiPIP, and cyt c_y ; and (3) enzymes of the periplasmic space such as NO_3^- , NO_2^- , N_2O , and DMSO reductases. With O_2 as final electron acceptor, the NQR, QCR, and COX enzymes constitute three main coupling sites where the potential energy between the initial donor and the final acceptor molecules is released in small steps that are controlled by the differences between the redox mid-point potentials (E_m) of the redox couples involved, and efficiently coupled to the generation of an electrochemical proton gradient ($\Delta\mu_{H^+}$). Photosynthesis converts the radiant energy into chemical energy at the level of the photochemical reaction center (RC). This transmembrane protein complex generates a charge separation that is followed by a cyclic electron transfer involving quinone molecules (UQ-10), cyt bc_1 complex, and soluble cyt c_2 in addition to the membrane-bound cyt c_y , in the case of *Rba. capsulatus*. Under dark aerobic conditions, facultative phototrophs use a respiratory chain, closely related to that present in mitochondria. The last step of O_2 reduction into H_2O is catalyzed by two oxidases (not always present in a single species): a cyt c oxidase (of cbb_3 and/or aa_3 type), inhibited by μM cyanide, and a quinol oxidase (of bo type), inhibited by mM cyanide, branching the electron flow at the level of the UQ-10 pool. **Figure 1** shows a block scheme of the different electron-transport pathways operating in *Rba. sphaeroides*.

Interaction between the Diverse Electron Transport Chains

The interaction between the different bioenergetic chains of photosynthetic bacteria occurs by two nonexclusive mechanisms, namely: (1) an indirect mechanism, exerted by the proton motive force (PMF) as a back pressure on the rate of electron transport catalyzed by redox complexes and (2) a direct mechanism of interaction between electron carriers, for example, UQ-10 or cyt c_2 , that are engaged in multiple bioenergetic processes. In this way, the activity of a given bioenergetic chain would affect the redox state of the components in common and, consequently, the functioning of the other chains.

the phosphorylation of RegA which results in the activation of photosynthesis.

In the other well-studied species, *Rba. sphaeroides*, the sensing of the oxygen tension relies, instead, on the terminal oxidase *cbb₃*, which is able to detect changes in the flux of electrons. High electron flow, in the presence of oxygen, represses the PrrA/PrrB system which results in the induction of respiration and the repression of photosynthesis. On the contrary, low electron flow, due to low oxygen, stimulates PrrA/PrrB to induce the photosynthetic-anaerobic metabolism. Depending on its phosphorylated or dephosphorylated status, the RegA/RegB (PrrA/PrrB) couple can regulate the expression of a considerable number of genes involved in important metabolic processes in addition to respiration and photosynthesis: N₂ fixation, CO₂ fixation, and H₂-ase activity. The electron transport chain (ETC) genes that have been shown to be regulated by RegA/RegB (in *Rba. capsulatus*) and PrrA/PrrB (in *Rba. sphaeroides*) are the ones coding for COX and QOX, which are specific for the respiratory chain, and those coding for the *bc₁* complex, cyt *c₂* and cyt *c_v*, which participate in both respiration and photosynthesis (Figure 2). Other regulatory elements that participate in the regulation of respiratory ETC components are AerR, that operates in the presence, as well as in the absence, of O₂; HvrA and FnrL are anaerobic regulators only (Figure 2). Although the interaction of all the afore-mentioned regulatory elements is quite complex, it allows the fine tuning and controlled interplay of respiratory and photosynthetic activities.

Oxygenic Micrororganisms

Cyanobacteria are capable of oxygenic photosynthesis, differing in that from anoxygenic phototrophs. Cyanobacteria form one of the major phyla of Bacteria and they were most likely the first oxygen-evolving organisms on Earth changing the atmosphere from anoxic to oxic. Cyanobacteria are grouped into several morphological groups; however, most of the available biochemical and genetic data concern mainly unicellular genera such as *Synechococcus* and *Synechocystis*.

Respiration is by definition a membrane-bound process; in this respect, cyanobacteria contain three different types of membranes: (1) the outer membrane, typical of Gram negatives, which has no specific role in respiration; (2) the cytoplasmic membrane (CM) also called 'periplasmic membrane (PM)' and (3) the intracytoplasmic membranes (ICMs) also called 'thylakoid membranes (TMs)'. Both CM and TM contain respiratory redox complexes; electron microscopy also indicates that CM and TM might be connected, at least in *Synechococcus* sp. strain PCC 6301, although a correct picture of the membrane arrangement *in vivo* is lacking at present.

Electron Transport Pathways in Cyanobacteria

Respiratory and photosynthetic electron transports are intimately connected in two distinct bioenergetically active membranes, TM and CM. All photosynthetic electron transport is located in the TM, where photosynthesis and respiration share components (Figure 3). In addition, ample experimental

evidences indicate the presence of respiratory chain(s) in the CM. Cyanobacterial respiratory terminal oxidases (RTOs) have no direct function in photosynthesis and therefore can be considered the key enzymes of respiration. All cyanobacteria (investigated so far) contain several respiratory branches ending in different RTOs but their actual location in the membrane cell (TM, CM, or both) is far from being assessed. The best-characterized species is *Synechocystis* sp. strain PCC 6803, for which the complete genomic sequence is available. Three sets of genes for RTOs were found, the well-characterized *aa₃*-type cyt *c* oxidase (COX, encoded by *coxBAC*), a related set of genes also belonging to the heme-copper oxidase superfamily, termed 'alternate RTO (ARTO; encoded by *ctaCII-ctaDIIIEII*), and two genes (*cydAB*) encoding a putative cyt *bd*-type quinol oxidase (Cyd).

Two types of nicotinamide adenine dinucleotide phosphate (reduced form) (NAD(P)H) dehydrogenases have been found. One is a NADPH-type I dehydrogenase (NDH-1), that is encoded by *ndh* genes, which consists of about 12 subunits and contributes to a proton gradient ($\Delta\mu_{H^+}$) across the membrane. The second type of dehydrogenase is a NADH-type II dehydrogenase (NDH-2) consisting of a single subunit and probably not contributing to energy transduction. In *Synechocystis* sp. strain PCC 6803, three genes coding for NDH-2 (*ndbA,B,C*) are found.

The CM forms the inner boundary of the periplasmic space and is known to contain proteins typically associated with respiratory electron transport, such as NAD(P)H dehydrogenase of type II, succinate dehydrogenase (SDH), and terminal oxidases, presumably ARTO and/or QOX (quinol oxidases: Cyd or Cta II). Three intermingling pathways are dominant in *Synechocystis* sp. strain PCC 6803 thylakoids (TM), namely: (1) a linear electron transport from H₂O to NAD(P)H, catalyzed by photosystems I and II (PSI/PSII), (2) a respiratory transport from NAD(P)H and succinate to both COX of *aa₃*-type (Cta I) and QOX of *bd*-type (Cyd), and (3) a cyclic electron flow around PSI, that is, electrons at the acceptor side of PSI returning to the PQ pool by means of a soluble ferredoxin (Fd) (Figure 3). However, as generally seen in facultative anoxygenic phototrophs, (Figure 1) electrons can move from one pathway to another at the level of the PQ pool, *b₆/f* complex (homologous of the *bc₁* complex), and/or soluble carriers such as plastocyanin (PC) or cyt *C₆* (previously known as cyt *c-553*) (Figure 3). For example, in the absence of PSI, reducing equivalents generated by PSII are fed into COX, while in darkness, respiratory electrons are used to reduce the acceptor side of PSII if terminal oxidases are blocked. Results with mutants of *Synechocystis* sp. strain PCC 6803 impaired in several combinations of respiratory and photosynthetic redox complexes indicate that SDH is the main electron transfer pathway into the PQ pool and that type I and II NAD(P)H dehydrogenases might simply operate as regulators of NADP⁺ and NAD⁺ reduction levels. This suggests that respiration in cyanobacteria plays an important role in the control of the intracellular redox balance.

In general, the genes for components of the respiratory chain(s) are present in only one copy per chromosome even in those species having two respiratory chains (Figure 3). How one gene directs its gene product into two different membranes (CM and TM) is an intriguing yet unanswered question. Further, the amounts of several components of the respiratory

Figure 3 Working model of photosynthetic and respiratory electron transport chains in CM and TM of *Synechocystis* sp. strain PCC 6803. Membrane-bound redox complexes are indicated as rectangular boxes. A dotted arrow from NAD(P)H to PQ (CM redox chain) symbolizes the lack of evidence for electron flow at this level; the thickness of arrows in TM redox chains is indicative of their relative activities. Abbreviations: HQNO, 2-heptyl-4-hydroxy-quinoline-N-oxide; PCP, pentachlorophenol; CN^- , cyanide anion; PC, plastocyanin; PQ, plastoquinone pool; $h\nu$, radiant energy; see also text for further details.

chain(s) are regulated by external factors such as the concentration of Cu^{2+} for synthesis of cyt C_6 and PC or the ionic strength for cyt aa_3 -type oxidase synthesis. Unfortunately, the mechanisms of gene regulation are largely unknown at present and they will be important topics for future studies in respiration of oxygenic phototrophs.

Glossary

Binuclear center A binuclear center comprises two redox-active components in close proximity, for example, copper and cytochrome *a* or two-iron atoms linked by an oxygen atom that function as a single entity to mediate electron transfer.

Proton-motive force The energy contained in an electrochemical gradient of protons across the inner mitochondrial membrane/thylakoid membrane and composed of two components, the membrane potential

and pH gradient. It is the driving force for the transport of substrates across the membrane and for the synthesis of adenosine triphosphate.

Proton pump A transmembrane protein which mediates the active transport of protons across the inner mitochondrial membrane/thylakoid membrane.

Respiratory chain An assemblage of electron carriers normally arranged as a multicomponent complex and located in the inner mitochondrial membrane.

Components of the Respiratory Chain

The respiratory chain and adenosine triphosphate (ATP) synthase are, in eukaryotic cells, located in the inner membrane of mitochondria. Mitochondria are oval-shaped organelles, typically 1–2 μm long and 0.5 μm in diameter, whose principal cellular functions are to generate energy, in the form of ATP and carbon skeletons for biosynthetic purposes. The shape and appearance of mitochondria vary considerably and these organelles appear to be most numerous in mammalian tissues with a high-energy demand (heart, liver, muscle, and brain and in rapidly dividing plants cells). The respiratory chain functions to oxidize NADH ($+H^+$) and $FADH_2$ and reduce molecular oxygen to water. These functions are electron transfer (electron motive) processes and result in a substantial release of energy, which generates a proton-motive force that is used to drive the ATP synthase in the forward direction thereby synthesizing ATP for use in cellular reactions.

The conversion of the electron-motive force (NADH and $FADH$ oxidation) into a proton-motive force is carried out by three electron-driven proton-pumping respiratory chain complexes. These large transmembrane complexes contain numerous reduction–oxidation (redox) components that include flavins, iron–sulfur proteins, cytochromes, ubiquinone, and metal ions.

Flavins

Flavin mononucleotide (FMN) and flavin dinucleotide (FAD) are tightly bound (to their enzymes) cofactors that can accept (or donate) two electrons and two protons (to become fully reduced) or a single electron and proton to form the semiquinone intermediate.

Iron–Sulfur Proteins

Iron–sulfur (or nonheme iron) proteins contain iron atoms covalently bound to the apo-protein by cysteine sulfurs and to other iron atoms via acid labile sulfur bridges. In general, there are three types of iron–sulfur proteins, namely, a single iron atom coordinated to the sulphydryl groups of four

cysteine residues of the protein, a protein containing two irons and two inorganic sulfides ($2Fe-2S$), and four irons and four inorganic sulfides ($4Fe-4S$). Similar to the single iron cluster, both are coordinated by four cysteine residues. All three types of iron–sulfur proteins can act as single electron carriers.

Cytochromes

Cytochromes are proteins containing a prosthetic group called a 'heme'. The basis of the heme is a porphyrin, which consists of four pyrrole rings linked in a cyclic manner by methene bridges with a central coordinated iron atom that acts as a single electron carrier. There are at least four classes of cytochromes (cytochrome A–D) differentiated from each other by the ability to absorb light at different wavelengths (due to differences in the side chains on the porphyrin).

Ubiquinone

Ubiquinone or coenzyme Q is a hydrophobic quinone derivative that in mammalian mitochondria has a side chain of 10 five-carbon isoprene units (Q_{10}). Ubiquinone can be fully reduced to the quinol form by the acceptance of $2H^+$ and $2e^-$ (or the semiquinone derivative can be formed through the acceptance of a single proton and electron).

Respiratory Chain Complexes

The following respiratory chain complexes (I, III, and IV) are associated with proton translocation across the inner mitochondrial membrane.

Complex I (NADH–Ubiquinone Oxidoreductase)

NADH–ubiquinone oxidoreductase is the largest (~ 1 MDa) and most complicated of the respiratory chain complexes, having ~ 43 subunits. Although it is well established that complex I contains FMN and 8–9 iron–sulfur proteins as redox centers, the exact route of electron transfer is uncertain. What is certain, however, is that the enzyme transfers two

protons and two electrons from NADH ($+H^+$) to ubiquinone, and electron transfer is accompanied by the translocation of protons across the membrane with a stoichiometry of $4H^+/2e^-$. Enzyme activity is potentially inhibited by rotenone and piericidin A. Although a crystal structure for complex I is yet to be solved, single particle electron microscopic studies suggest that the complex has an L-shape with the majority of the redox centers being located within the peripheral hydrophilic part of the enzyme. The exact mechanism whereby protons are translocated across the membrane is uncertain.

Complex III (Ubiquinone–Cytochrome *c* Oxidoreductase or the *bc*₁ Complex)

Complex III is a large (~250 kDa) multicomponent complex that catalyzes the oxidation of ubiquinol and the reduction of cytochrome *c*₁ and results in the vectorial transport of protons across the inner mitochondrial membrane. Redox centers include a 2Fe–2S protein (the Rieske center), two *b* cytochromes (cytochrome *b*_L and *b*_H), and cytochrome *c*₁. X-ray crystallography studies reveal that the enzyme is dimeric, with each of the two monomers being composed of at least 11 subunits (eight of which appear to have no catalytic role). Crystallography has also revealed that the monomers do not function independently but cooperate during electron transfer. Structural studies have also shown that the Rieske center shuttles between the quinone-binding site (of one of the monomers) in its oxidized state and cytochrome *c*₁ (of the second monomer) in its reduced state. Although the pathway of electron flow through complex III (known as the Q-cycle) is complicated, the net equation is

where N and P refer to the negative and positive sides, respectively, of the membrane (Figure 1).

The Q-cycle accommodates the fact that there is a mixture of two and one electron carriers and hence there must be a switch between ubiquinol (a two-electron carrier), the

cytochromes, and Rieske center (all of which are single-electron carriers). It also explains the well-documented observation that the H^+/e^- stoichiometry for the *bc*₁ complex is 4. Complex III is inhibited by antimycin A, myxothiazol, and stigmatellin.

Complex IV (Cytochrome *c*–Oxygen Oxidoreductase or Cytochrome *c* Oxidase)

Complex IV is a third large transmembrane enzyme (204 kDa) that catalyzes the oxidation of reduced cytochrome *c* and the reduction of molecular oxygen to water. It is also associated with the translocation of protons across the membrane and has at least 13 subunits of which only subunits I and II appear to play a role in catalysis. The complex contains three Cu atoms and two heme *a* (cytochrome *a* and cytochrome *a*₃). High-resolution structural studies reveal that subunit II contains two of the Cu atoms complexed with sulfur atoms to form a binuclear center (known as 'Cu_A center'). Subunit I contains the two cytochromes and the third Cu atom (Cu_B), which is closely associated with cytochrome *a*₃ forming a second binuclear center. Electron transfer through complex IV is from cytochrome *c* to the Cu_A center (which acts as a single-electron receptor), then to heme *a* (which is slightly closer to the Cu_A center than heme *a*₃) onto the heme *a*₃–Cu_B center and finally onto oxygen bound to heme *a*₃. For every four electrons passing through the complex, one molecule of oxygen is reduced to two molecules of water, four protons are consumed from the matrix, and four protons are translocated across the membrane. It should be noted that the four-electron reduction of molecular oxygen occurs as four single electron events and hence it is important that the potentially dangerous partially reduced intermediates such as superoxide anion are not released but remain tightly bound until completely reduced to water. Cytochrome *c* oxidase is potentially inhibited by cyanide, azide, and carbon monoxide, which bind at the oxygen-binding site. Nitric oxide is also a reversible inhibitor of this complex.

Figure 1 A schematic representation of the respiratory chain. The P- and N-sides of the membrane refer to the intermembrane space (positive) and matrix (negative), respectively. ND_P and ND_N refer to NADH dehydrogenases (such as the ETF, glycerol-3-phosphate, and externally located NADH dehydrogenases) located on the P- and N-sides, respectively. AOX is the alternative oxidase.

Other Ubiquinone-Reducing Enzymes

Animal, plant, and a number of protist mitochondria also contain a number of membrane-bound enzymes that can reduce ubiquinone. These enzymes do not transfer charge across the membrane, that is, protons are not vectorially transported across the inner mitochondrial membrane and are detailed in the following section.

Succinate dehydrogenase

Succinate dehydrogenase is the only membrane-bound enzyme of the citric acid cycle that interacts directly with the respiratory chain. Succinate dehydrogenase is much smaller than complex I (~140 kDa) being composed of four subunits. The two larger of these subunits are peripheral proteins that contain covalently bound FAD (on subunit I) and three iron-sulfur centers (on subunit II). These two large subunits are anchored to the inner surface of the inner membrane by two integral membrane polypeptides (subunits III and IV) in which a single heme *b* is located. Although the exact route of electron transfer from succinate to ubiquinone is uncertain, it is known that the reduction of ubiquinone by succinate is not associated with any charge movement.

Electron-transferring flavoprotein-ubiquinone reductase

The electron-transferring flavoprotein (ETF)-ubiquinone oxidoreductase is a globular protein located on the inner surface of the inner membrane and contains FAD, an Fe-S center, and a ubiquinone-binding site. The enzyme can accept reducing equivalents from a variety of dehydrogenases including those involved in fatty acid oxidation or amino acid and choline catabolism.

Glycerol-3-phosphate dehydrogenase

Glycerol-3-phosphate dehydrogenase is located on the outer surface of the inner membrane and catalyzes the oxidation of glycerol-3-phosphate to dihydroxyacetone phosphate and the reduction of ubiquinone. Although little is known about the structure or the route of electron transfer to ubiquinone, redox centers include FAD and probably an iron-sulfur center.

External NADH dehydrogenase

There are a number of rotenone-insensitive NADH dehydrogenases located on the outer and inner surface of the inner mitochondrial membrane in plant and yeast mitochondria. Again, there is little structural information apart from the presence of FAD and possibly an iron-sulfur center. Electron transfer is probably similar to that described for the ETF-ubiquinone oxidoreductase since the enzyme catalyzes the oxidation of NADH and the reduction of ubiquinone. In plants, the external NADH dehydrogenase (on the outer surface of the inner membrane) is regulated by cytosolic Ca^{2+} . These enzymes are not associated with proton pumping across the mitochondrial membrane.

Other Ubiquinol-Oxidizing Enzymes (the Alternative Oxidase)

Although mammalian mitochondria do not possess any other ubiquinol-oxidizing enzymes apart from cytochrome oxidase (complex IV), most plants, some yeasts, fungi, and trypanosomes possess a cyanide- and antimycin-insensitive alternative oxidase that catalyzes the oxidation of ubiquinol and reduces

molecular oxygen to water. Unlike cytochrome *c* oxidase, electron transfer does not result in proton translocation and the redox energy is released as heat. Spectroscopic and recent preliminary crystallographic studies indicate that the enzyme contains two nonheme iron atoms linked by an oxygen atom as its only redox carrier (di-iron protein) and is globular with two of its amphiphilic helices lying parallel to the membrane plane. Enzyme activity is insensitive to all complex IV inhibitors but can be potentially inhibited by salicylhydroxamic acid, alkyl gallates, and ascofuranone.

Organization of the Respiratory Chain

The respiratory chain complexes in mammalian and plant mitochondria are generally considered to be free to diffuse laterally and independently of each other within the plane of the membrane. They are connected electronically to each other by ubiquinone and cytochrome *c* with electron transfer occurring by diffusion-based collisions between these components. There is also evidence to suggest that the number of complexes within the membrane are unequal with the following ratio: complexes I:II:III:IV: cytochrome *c*: ubiquinone = 1:2:3:7:14:63. Both cytochrome *c* and ubiquinone are considered to function as common pools and hence act as mobile carriers mediating electron transfer between freely diffusible large respiratory complexes. In contrast to this fluid-state model, however, there is evidence for a solid-state model in which stable interactions are believed to occur between some of the respiratory chain complexes resulting in the formation of supercomplexes.

In both cases, however, for every $2e^-$ passing from NADH ($+H^+$) to oxygen to produce one molecule of water a total of 10 protons are released at the P-side of the membrane. Since four protons are required to synthesize and export one ATP, the amount of ATP formed by the oxidation of NADH is 2.5 (1.5 for succinate).

The ATP Synthase

The ATP synthase (or F_1F_0 ATPase and also referred to as 'complex V') uses the free energy of an electrochemical gradient of protons (or sodium ions) generated by the respiratory chain to synthesize ATP. The ATP synthases comprise a very large group of highly conserved enzymes that are found in the bacterial cytoplasmic membranes, the thylakoid membranes of chloroplasts, and the inner membranes of mitochondria. Most members of the group use H^+ as the coupling ion (the *Propionigenium modestum* enzyme is an example of the few ATP synthases that can use Na^+ as the physiological coupling ion).

Structure of the ATP Synthase

The ATP synthase is a miniature rotating motor and the simplest or prototype enzyme is that isolated from *Escherichia coli*. The enzyme has a bipartite structure composed of a membrane-bound (hydrophobic) F_0 component crossing the inner mitochondrial membrane and a water-soluble (hydrophilic) F_1 component that protrudes into the mitochondrial matrix.

The F_0 component

The F_0 entity is composed of three subunits (a , b , and c) with a stoichiometry of: $a:2b:9-12c$ and it functions as a proton channel. The proton channel is a ring of 9–12 c subunits (the number of subunits may depend on the carbon source used for growth) positioned in the membrane and tightly bound to one a -subunit plus two b -subunits of F_0 and also bound to the γ , δ , and ϵ subunits of the F_1 component of the synthase. The F_1 component is also attached to F_0 by the peripheral stalk or stator, an assembly of single copies of subunits b and d , oligomycin sensitivity conferral protein (OSCP), and F_6 .

The F_1 component

The F_1 component has five types of subunits (α , β , γ , δ , and ϵ) with a stoichiometry of $3\alpha:3\beta:\gamma:\delta:\epsilon$. The $\alpha_3\beta_3$ subunits are arranged as a hexamer of alternating α - and β -subunits with the γ -subunit projecting into the central cavity of this hexamer. The β -subunits contain the catalytic site for ATP synthesis/hydrolysis and bind the adenylates and inorganic phosphate.

ATP synthases from other sources all have very similar structures to the *E. coli* synthase except the mitochondrial enzyme. It contains an inhibitor protein (IF₁) and the OSCP factor. The mitochondrial δ -subunit is related to the ϵ -subunit of the *E. coli* synthase (Figure 2).

Mechanism of ATP Synthesis

ATP synthesis is driven by the rotation of the single γ -subunit, which extends into the center of the $\alpha_3\beta_3$ hexamer that contains the catalytic sites. As the single γ -subunit rotates so it alternately changes the conformation (and hence binding characteristics) of the catalytic sites. Changes in nucleotide affinity occur in the three β -subunits and arise from their

interactions with the γ -subunit. This results in the sequential binding of adenosine diphosphate (ADP) and P_i , followed by ATP synthesis and ATP release. This concept recognizes that the β -subunit can exist in three conformations: open, tight, or loose forms. These forms correspond to the binding, synthesis, and release of ATP and are driven by the rotation of the γ -subunit. The hydrolysis of ATP will drive the rotation of the γ -subunit in the opposite direction to that of synthesis.

Subunits c_{9-12} , γ , and ϵ constitute the rotor (rotating unit) and subunits α_3 , β_3 , δ , a , and b_2 constitute the stator or peripheral stalk (stationary unit). The proton-motive force drives rotation of the oligomeric ring of the c -subunits and of the γ -subunit in F_0 (since the γ -subunit is attached to the c -oligomer). Thus, protons moving from the P-side to the N-side of the inner membrane (i.e., down the electrochemical gradient) are converted into rotational torque of γ , which alters nucleotide binding at the β -catalytic site and results in the synthesis/hydrolysis of ATP. It is not the synthesis of ATP but its release from the synthase that is driven by the proton-motive force. Subunits γ and ϵ rotate relative to the $\alpha_3\beta_3$ hexamer to alter the nucleotide affinities (and hence binding) in the β -catalytic sites. Probably subunit γ of F_1 and two copies of subunit b in F_0 stabilize the synthase complex.

A simplified mechanism suggests that it is the flow of protons through c via a channel (or two half channels) that protonates an aspartate residue and the proton is released through the channel (or second half channel). Conformational changes during this cycle of protonation–deprotonation provide the basis to explain rotation. This protonated c subunit then rotates through 360° during ATP synthesis/hydrolysis and both the subunits γ and ϵ rotate by 120° for each ATP synthesized (or hydrolyzed) with the rotation being coupled to the protonation–deprotonation of three–four c subunits.

Glossary

Accessory subunits Subunits of mostly eukaryotic respiratory chain complexes that are not considered to be essential for the bioenergetic core function, because they are not present in fully functional prokaryotic complexes. The function of most accessory subunits remains unclear, but involvement in assembly, stability, and regulation has been proposed.

Iron–sulfur clusters Nonheme iron prosthetic groups found in a wide range of redox enzymes. The reduced forms of binuclear and tetranuclear iron–sulfur clusters are paramagnetic and can be studied by electron-paramagnetic-resonance (EPR) spectroscopy.

Mitochondrial DNA Small genome that codes for 13 subunits of the respiratory chain complexes and adenosine triphosphate (ATP)-synthase. A typical mammalian cell

contains several hundreds of mitochondria and several thousands of mitochondrial genomes that are inherited exclusively through the oocyte cytoplasm.

Oxidative phosphorylation (OXPHOS) The fuel cell of aerobic metabolism. Process by which redox energy derived from reduced nicotinamide adenine dinucleotide (NADH) or reduced flavin adenine dinucleotide (FADH₂) is converted into the phosphorylation potential of ATP. Electron transport and ATP-synthesis are energetically coupled through an electrochemical proton potential across the inner mitochondrial membrane.

Reactive oxygen species (ROS) Superoxide (O₂^{•−}), hydrogen peroxide (H₂O₂), and hydroxyl radical (OH[•]) that may cause severe damage to lipids, proteins, and DNA. In mitochondria, ROS are generated by side reactions of the respiratory chain complexes.

Introduction to Complex I

Complex I (EC 1.6.5.3) is a multi-subunit respiratory chain reduced nicotinamide adenine dinucleotide (NADH):ubiquinone oxidoreductase that is found in the inner mitochondrial membrane of almost all eukaryotes and in the plasma membrane of many bacteria. It contains one molecule of flavin mononucleotide (FMN) and eight to nine iron–sulfur clusters as redox prosthetic groups.

Mammalian complex I couples the transfer of two electrons to the pumping of four protons across the mitochondrial inner membrane and thereby provides up to 40% of the driving force for adenosine triphosphate (ATP) generation by oxidative phosphorylation (OXPHOS). Complex I is the target of numerous pathological human mutations in both the mitochondrial and the nuclear genomes. Single electron transfer is part of its catalytic cycle and complex I is considered a major source for reactive oxygen species (ROS) that have been implicated in the etiology of neurodegenerative disorders and in aging.

Complex I Structure

Overall Shape

Electron microscopic analysis using single particles and two-dimensional (2D) crystals has demonstrated that the enzymes from mammalian and fungal mitochondria as well as eubacteria are L shaped with a hydrophobic membrane integral arm and a hydrophilic peripheral arm that protrudes into the mitochondrial matrix or the bacterial cytoplasm, respectively (Figure 1).

The X-ray structure of a peripheral arm fragment of complex I from the eubacterium *Thermus thermophilus* was solved at up

to 3.1-Å resolution. Lower-resolution crystallographic data permitted to construct an α -helical model for the major part of the membrane arm of complex I from *Escherichia coli* and to define the overall architecture of the complete enzyme complex from *T. thermophilus*. X-ray crystallographic analysis of complex I from the aerobic yeast *Yarrowia lipolytica* revealed the arrangement of functional modules in the much larger and more complex eukaryotic enzyme. Complex I from different species was shown to assemble into supercomplexes with respiratory complexes III and IV.

Central Subunits and Redox Clusters

The minimal form of complex I that is found in bacteria such as *T. thermophilus* typically consists of 14 subunits. These central subunits are conserved throughout in prokaryotes and eukaryotes and can be assigned to three main modules according to their bioenergetic core functions: (1) NADH oxidation (N-module), (2) ubiquinone reduction (Q-module), and (3) proton translocation (P-module) (Table 1).

The N-module and the Q-module contain the seven hydrophilic central subunits and all redox prosthetic groups namely one molecule of FMN and eight to nine iron–sulfur clusters. At present, their nomenclature is a matter of debate and there is only partial agreement on the assignment of electron-paramagnetic-resonance (EPR) signatures to individual iron–sulfur clusters (Table 1). The N-module resides in the distal and the Q-module in the proximal part of the peripheral arm (Figure 1). The primary electron acceptor FMN in the N-module is connected via a chain of iron–sulfur clusters with the ubiquinone reduction site near cluster N2 in the Q-module. For this cluster, a remarkable distance of about

Figure 1 Schematic representation of mitochondrial complex I. The peripheral arm contains the seven nuclear-encoded central subunits and harbors all known redox prosthetic groups. The membrane arm contains the seven mitochondrially encoded subunits which are all highly hydrophobic. Eukaryotic complex I contains a number of additional accessory subunits distributed over both arms. A chain of iron–sulfur clusters (red spheres) connects the NADH oxidation site in the N-module with the ubiquinone reduction site near cluster N2 in the Q-module. One cluster may serve a special function in protection against formation of reactive oxygen species at the flavin site. The energy of the redox reaction drives vectorial proton translocation across the inner mitochondrial membrane. The proton translocation sites must be located in the membrane arm that is subdivided into a proximal P_P and a distal P_D domain. The architecture of complex I excludes direct coupling between electron transfer and proton pumping and rather suggests the transmission of energy via conformational changes. The helical element (magenta) connecting the P_P and P_D domains may play a crucial role in a conformational coupling mechanism.

30 Å to the membrane plane has been reported for eukaryotic complex I, very similar to the arrangement described for the prokaryotic enzyme. The flavin site of complex I has been identified as a major source of ROS. Cluster N1a in the N-module is not lined up in the long electron transfer chain with the other iron–sulfur clusters and might rather serve a critical function in protection against excessive ROS formation. The P-module contains the seven hydrophobic subunits ND1–ND6 and ND4L that are encoded by the mitochondrial genome in most eukaryotes. Based on recent structural evidence, the P-module can be subdivided into a proximal and a distal domain, P_P and P_D respectively. These two domains are connected by an extended helical element laterally associated with the membrane arm (Figure 1, magenta). This unprecedented structural feature has been suggested to serve as a transmission element for conformational energy (see section Proton Pumping).

Accessory Subunits

Eukaryotic complex I also contains a large number of additional so-called accessory subunits, resulting in a total number of more than 35 subunits in fungi and at least 45 subunits in mammals. While some of these subunits may simply serve as a scaffold to increase the stability of the enzyme, there are

indications that others may confer additional features specific to eukaryotic complex I. Some examples include the following: the acyl carrier protein (ACP) carries a phosphopantetheine prosthetic group and may function in the biosynthesis of lipoic acid or in mitochondrial lipid metabolism; several subunits of purified bovine complex I were found to be phosphorylated (42-kDa, ESSS, MWFE, B14.5a, B14.5b, and B16.6); phosphorylation at a cyclic adenosine monophosphate (cAMP)-dependent protein kinase consensus site of the AQDQ subunit stimulates complex I activity, presumably by promoting the import of this nuclear-encoded protein into mitochondria and assembly into the mature enzyme complex; the B16.6-kDa subunit is identical with the programmed cell-death-regulatory GRIM19 protein and may link complex I function to apoptosis; and the MWFE subunit of the membrane arm seems to be involved in complex I assembly. Overall, very little is known about the function of the accessory subunits.

A nomenclature established for the bovine enzyme by John Walker and co-workers has been generally accepted for these complex I subunits and their orthologs found in other organisms: Apart from some of the nuclear-coded subunits that were originally named by their molecular masses, the first four amino acids of the mature protein are used (Table 1). If the mature protein is N-terminally blocked, a number indicating the molecular mass preceded by the letter B identifies the subunit.

Complex I Assembly

The multistage assembly pathway of complex I is still only partially understood. In mutants of *Neurospora crassa*, deletion of two genes coding for CIA30 and CIA84 (for Complex I Associated) proteins led to complex I assembly defects. For human complex I, five assembly factors, NDUFAF1–NDUFAF4 and Ecsit have been identified. NDUFAF1 is the CIA30 homolog. In addition, Ind1 was shown to be essential for efficient assembly of complex I in the yeast *Y. lipolytica* and in humans. For identifying these factors, the complex one phylogenetic profile (COPP) approach, that is, the search for genes only present in species containing complex I, has proven very useful. The involvement in complex I assembly of several other proteins including the apoptosis-inducing factor (AIF) is unclear.

Complex I Evolution

Complex I was assembled from at least three preexisting structural and functional modules during evolution. The homology to [NiFe] hydrogenases from various archeal and eubacterial sources has been especially useful for the understanding of complex I.

Evolution of the Q-Module

Water-soluble hydrogenases from *Desulfovibrio* species consist of a large subunit which carries the [NiFe] site and is homologous to the 49-kDa subunit of complex I, and a small subunit which carries three iron–sulfur clusters and is homologous to the PSST subunit of complex I. In membrane-bound [NiFe] hydrogenases, exemplified by the enzyme encoded by the *ech* operon in *Methanosarcina barkeri*, the PSST homolog has

Table 1 The 14 central subunits of complex I; eukaryotic complex I contains a large number (31 in bovine heart) of additional accessory subunits

^aSubunits ND1–ND6 and ND4L and NU1M–NU6M and NULM are encoded by mitochondrial genome.

^bTo avoid confusion and to simplify general discussions we use the nomenclature for bovine complex I also for central subunits of the enzyme from *Y. lipolytica*.

^cThe nomenclature and assignment of EPR signatures to individual [Fe₄S₄] clusters in the TYKY and 75-kDa subunits is discussed controversially.

^dCompare Figure 1.

^eIn many bacteria this subunit contains one additional [Fe₄S₄] cluster.

^fNuoC and NuoD are fused to a single polypeptide in *E. coli*.

suffered a C-terminal deletion abolishing two iron–sulfur clusters. Instead, an additional subunit carrying two iron–sulfur clusters in a ferredoxin-like fold has been acquired in this type of hydrogenase that is homologous to the TYKY subunit of complex I. Recent structural evidence confirmed the close relationship between water-soluble [NiFe] hydrogenases and the 49-kDa and PSST subunits of complex I. It follows that a significant part of the ubiquinone reduction site of complex I has been derived from the [NiFe] site in the large subunit, while cluster N2 corresponds to the proximal iron–sulfur cluster in the small subunit of water-soluble hydrogenases. Critical residues for binding of ubiquinone and inhibitors were identified by site-directed mutagenesis in the yeast *Y. lipolytica*.

Evolution of the N-Module

The electron input device of complex I is related to the nicotinamide adenine dinucleotide (NAD)⁺ reducing [NiFe] hydrogenase from *Ralstonia eutropha*, encoded by the *hox* operon. The 24- and 51-kDa subunits are homologous to HoxF and the first 200 residues of the 75-kDa subunit are homologous to HoxU. The C-terminal half of the 75-kDa subunit shows sequence similarity to a formate dehydrogenase from *Methanobacterium formicicum*.

Evolution of the P-Module

Four subunits of the membrane arm of complex I are related to subunits of a multi-subunit bacterial monovalent cation/proton antiporter encoded by the *mrp* operon. Subunits ND5, ND4L,

and ND2 correspond to subunits MrpA, MrpC, and MrpD, respectively, while subunit ND4 may have originated from a duplication of the ND2-encoding gene. In contrast to ND4L, the three largest hydrophobic subunits of complex I, ND2, ND4, and ND5, display a certain degree of structural similarity.

Origin and Variants of Complex I

According to an evolutionary scheme suggested by Hägerhall and colleagues, complex I and membrane-bound hydrogenases originate from a common ancestor that comprised subunits derived from [Ni–Fe] hydrogenases (see section [Evolution of the Q-Module](#)), the antiporter homologs (see section [Evolution of the N-Module](#)), and the membrane-bound subunit ND1. Loss of the [Ni–Fe]-binding site and acquisition of the hydrophobic subunits ND3 and ND6 generated a 11-subunit-membrane-bound protein complex that can be regarded as the last common ancestor of classical complex I and variants with different electron input modules.

Two archaeal proton-pumping enzymes, F₄₂₀H₂:methanophenazine oxidoreductase from *Methanosarcina mazei* and F₄₂₀H₂:menaquinone oxidoreductase from *Archaeoglobus fulgidus* accept electrons from coenzyme F₄₂₀, which is specific for methanogenic archaea. The metabolic function of complex I from cyanobacteria and the chloroplasts of higher plants is not known. It may catalyze electron transfer from either NADH, reduced nicotinamide adenine dinucleotide phosphate, or ferredoxin to plastoquinone.

Complex I from the bacteria *Helicobacter pylori* and *Campylobacter jejuni* lacks the 51- and 24-kDa subunits and contains a

modified version of the 75-kDa subunit. Therefore, it is likely that the electron donor to these enzymes is also not NADH.

Complex I Function

The overall reaction of respiratory chain complex I is the transfer of electrons from NADH to ubiquinone or menaquinone in some bacteria and the concomitant buildup of chemiosmotic membrane potential that in mammalian mitochondria contributes about 40% to the total proton-motive force generated during oxidative phosphorylation.

Electron Transfer and Redox Centers

The physiological reaction of complex I involves electron transfer from NADH via FMN onto a series of iron–sulfur clusters with E_{m7} values between -370 and -250 mV. The tetranuclear iron–sulfur cluster N2 ($E_{m7} -150$ mV) is generally regarded as the last redox center in this electron transfer chain and most likely is the immediate electron donor for ubiquinone. Electron transfer from NADH to artificial acceptors like ferricyanide or hexaammineruthenium(III)-chloride does not involve the quinone-binding site and can also be observed with a three-subunit subcomplex (flavoprotein, FP) of bovine heart complex I which consists of the peripheral arm subunits 51 kDa, 24 kDa, and 10 kDa.

Proton Pumping

Experimental data with intact mitochondria and submitochondrial particles indicate that complex I pumps protons with a stoichiometry of $4H^+/2e^-$. The mechanism how proton translocation is coupled to redox chemistry is still unknown. A large number of concepts and more or less detailed hypothetical mechanisms have been proposed over the last decades, but even the number of proton translocation sites remains an unresolved issue. Several lines of evidence indicate that the potential drop that releases the energy for proton pumping occurs during reduction of ubiquinone. A membrane-potential-dependent and inhibitor-sensitive semiquinone species in the vicinity of cluster N2 has been observed by Ohnishi and co-workers by EPR spectroscopy. The structural models recently obtained by X-ray crystallography demonstrate a spatial separation of the redox chemistry including the reduction of ubiquinone in the peripheral arm from the pumping modules in the membrane arm subunits. As there is evidence that even the distal membrane arm domain contributes to proton translocation, this architecture strongly suggests that complex I operates through a conformational coupling mechanism. The extended helical element connecting the two membrane arm domains (see section [Central Subunits and Redox Clusters](#)) has been suggested to serve a critical function for transmission of conformational energy.

Na⁺ Pumping by Bacterial Complexes I

It has been reported that in some bacteria complex I pumps sodium ions in addition or instead of protons across the plasma membrane, generating a sodium-motive force rather

than a proton-motive force. The relevance of these experimental data is discussed controversially. Most recently, a sodium/proton antiport activity has been suggested for some forms of bacterial complex I.

Inhibitors of Complex I

A plethora of structurally diverse hydrophobic compounds have been reported to inhibit complex I and are considered to interfere with ubiquinone binding. These inhibitors include naturally occurring antibiotics as well as synthetic insecticides and acaricides, also, a number of drugs such as amytal and meperidine, neurotoxins related to 1-methyl-4-phenyltetrahydropyridine (MPTP), and even detergents such as Triton X-100 and Thesit inhibit complex I. Kinetic studies suggested that these inhibitors can be grouped into three different classes that are represented by the well-known and widely used inhibitors DQA (2-decyl-4-quinazolinyl amine) and piericidin A (class I/A-type), rotenone (class II/B-type), and capsaicin (C-type). Except for capsaicin, all these inhibitors exert their inhibitory potential at I_{50} values in the nanomolar range. Competition experiments demonstrated that these inhibitors share one common binding domain with partially overlapping sites. In agreement with this observation, cross-resistance between DQA/piericidin A and rotenone is observed in inhibitor-resistant mutants.

Active–Deactive Transition

Mitochondrial complex I from a number of species is reversibly deactivated in the absence of substrates, and several catalytic cycles are needed to restore full activity. The selective exposition of a specific cysteine residue of subunit ND3 in the deactive form indicated that the active/deactive transition is linked to structural changes. The transformation into a dormant state under hypoxic conditions and its slow reversion to the fully active state during reoxygenation might be a protective mechanism against a burst of excessive ROS formation. Conversely, S-nitrosation of the deactive form in the presence of NO and oxygen radicals might be a pathophysiological event impeding the return of complex I into the active state.

Complex I in Disease

Genetic defects in complex I typically result in multisystem disorders with a wide spectrum of severities ranging from adult-onset exercise intolerance to fatal infantile lactic acidosis. Disease is often progressive. Exposure to complex I inhibitors has been described as one pathogenic mechanism in sporadic Parkinson's disease.

Mitochondrial Mutations

Deletions within the mitochondrial genome or point mutations in mitochondrial transfer RNA (tRNA) genes affect the function of several respiratory chain complexes simultaneously. Skeletal muscle biopsies from such patients typically show ragged red fibers caused by mitochondrial hypertrophy. The typical clinical phenotype of mitochondrial point mutations in

complex I genes is Leber's hereditary optic neuropathy (LHON), characterized by optic nerve atrophy or LHON plus dystonia (LDYT), characterized by additional lesions in the caudate and putamen. Ragged red fibers are not commonly observed in patients with isolated complex I defects.

Nuclear Mutations

Due to the large number of potential target genes, mutations affecting nuclear-coded subunits of complex I or assembly factors have been described only recently. The typical clinical picture is Leigh syndrome, a severe, early-onset neuromuscular disorder, associated with lactic acidosis, ataxia, hypotonia, spasticity, developmental delay, optic atrophy, and, in the terminal stage, degeneration of the basal ganglia. Sometimes, this is accompanied by hypertrophic cardiomyopathy. Such mutations were found in the 75-kDa, 51-kDa, 49-kDa, PSST, TYKY, and AQDQ subunits and in the assembly factor NDUF2.

Mechanisms of Complex I Pathology

Complex I dysfunction has several biochemical consequences which may be relevant for producing disease symptoms. (1) Feedback inhibition of the NADH-producing citric-acid cycle and pyruvate dehydrogenase complex results in elevated blood lactate levels. (2) Lowered OXPHOS efficiency will reduce ATP production. OXPHOS defects often show a remarkable degree of tissue and organ specificity. This has been explained by assuming different energetic thresholds, in descending order for optic nerve, neuronal cells, heart muscle, skeletal muscle, and liver. (3) Complex I is a major source for ROS and malfunctions of the enzyme may lead to increased oxidative stress as evident from the induction of manganese superoxide dismutase messenger RNA (mRNA) in complex I patients. ROS damage of complex I and the ND genes in the mitochondrial genome may result in a vicious cycle of mitochondrial damage. (4) Reduced mitochondrial energy production and elevated oxidative stress may lead to the opening of the mitochondria permeability transition pore, release of pro-apoptotic factors, and apoptotic cell death.

Poisoning of Complex I

The neurotoxin 1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine (MPTP), a synthetic meperidine analog, is able to rapidly and persistently induce symptoms of acute Parkinsonism in humans and other primates. MPTP is metabolized to 1-methyl-4-phenylpyridinium (MPP⁺) by the action of glial cell monoamine oxidase B. As MPP⁺ is a substrate for the dopaminergic reuptake pathway, it accumulates in the nigrostriatal dopaminergic neurons, where it causes a specific reversible inhibition of complex I. Strikingly, highly selective neurodegeneration

of the nigrostriatal dopaminergic system was also observed following chronic exposure of rats to the common complex I inhibitor rotenone. These results support the view that complex I deficiency may also be involved in the etiology of idiopathic Parkinsonism.

Glossary

Flavin adenine dinucleotide (FAD) A riboflavin-containing hydrogen acceptor molecule in the Krebs cycle and a coenzyme of some oxidation–reduction enzymes.

Fumarate A dicarboxylate anion ($^-\text{OOC}-\text{CH}=\text{CH}-\text{COO}^-$) that occurs as an intermediate compound in metabolic processes, most importantly in the citric acid cycle (Krebs cycle).

Heme group A complex organic red iron-containing pigment used by proteins to bind oxygen and/or electrons.

His ligand A histidine residue that participates in forming a complex around a central atom or ion, for example, the central iron of a heme group.

Succinate A dicarboxylate anion ($^-\text{OOC}-\text{CH}_2-\text{CH}_2-\text{COO}^-$) that occurs as an intermediate compound in metabolic processes, most importantly in the citric acid cycle (Krebs cycle).

Succinate:quinone oxidoreductases (SQORs; EC 1.3.5.1) are enzymes that couple the two-electron oxidation of succinate to fumarate (eqn [1]) to the two-electron reduction of quinone to quinol (eqn [2]):

They can also catalyze the opposite reaction, the coupling of quinol oxidation to the reduction of fumarate. Depending on the direction of the reaction catalyzed *in vivo*, the members of the superfamily of SQORs can be classified as either succinate:quinone reductases (SQRs) or quinol:fumarate reductases (QFRs). SQR and QFR complexes are anchored in the cytoplasmic membranes of archaeobacteria and eubacteria, and in the inner mitochondrial membrane of eukaryotes with the hydrophilic domain canonically extending into the cytoplasm and the mitochondrial matrix, respectively. SQR (respiratory complex II) is involved in aerobic metabolism as part of the citric acid cycle (Krebs cycle) and of the aerobic respiratory chain (Figure 1(a)). QFR participates in anaerobic respiration with fumarate as the terminal electron acceptor (Figure 1(b)), and is part of the electron transport chain catalyzing the oxidation of various donor substrates (e.g., H_2 or formate) by fumarate. These reactions are coupled via an electrochemical proton potential (Δp) to adenosine diphosphate phosphorylation with inorganic phosphate by adenosine triphosphate synthase.

SQOR Classification

Functional Classification

SQORs can be divided into three functional classes based on the quinone substrate and the *in vivo* function of the enzyme. Subclass 1 contains those enzymes that oxidize succinate (with an oxidation–reduction potential at pH 7, $E_{\text{M7}} = +25$ mV) and reduce a high-potential quinone, for example, ubiquinone ($E_{\text{M7}} = +90$ mV) or caldariella quinone ($E_{\text{M6.5}} = +103$ mV). The SQRs from mammalian mitochondria (respiratory complex II) and many prokaryotes belong to this group. Subclass 2 comprises all those enzymes that catalyze the oxidation of a

low-potential quinol, for example, menaquinol ($E_{\text{M7}} = -74$ mV) or rholoquinol ($E_{\text{M7}} = -63$ mV), and the reduction of fumarate. All QFRs studied so far belong to this subclass. Subclass 3 includes those enzymes that catalyze the oxidation of succinate and the reduction of a low-potential quinone, for example, menaquinone or thermoplasmaquinone. These subclass 3 enzymes are found in Gram-positive bacteria (e.g., *Bacillus subtilis*, *Paenibacillus macerans*, and *Bacillus licheniformis*) and archaeobacteria (e.g., *Thermoplasma acidophilum*).

Structural Classification

SQORs generally contain four protein subunits, referred to as A, B, C, and D. Subunits A and B are hydrophilic, whereas the subunits C and D are integral membrane proteins. Among species, subunits A and B have high sequence homology, while that for the hydrophobic subunits is much lower. Most of the SQR enzymes of Gram-positive bacteria and the QFR enzymes from epsilon-proteobacteria contain only one larger hydrophobic polypeptide (C), which is thought to have evolved from a fusion of the genes for the two smaller subunits C and D. Although subunit A harbors the site of fumarate reduction and succinate oxidation, the hydrophobic subunit(s) contain the site of quinol oxidation and quinone reduction.

Based on their hydrophobic domain and heme *b* content, SQORs can be classified into five types (Figure 2(a)). Type A enzymes contain two hydrophobic subunits and two heme groups, for example, SQR from the archaea *Archaeoglobus fulgidus*, *Natronomonas pharaonis*, and *Thermoplasma acidophilum*. Type B enzymes contain one hydrophobic subunit and two heme groups, as is the case for SQR from the Gram-positive bacteria *Bacillus subtilis* and *Paenibacillus macerans*, and QFR from the epsilon-proteobacteria *Campylobacter jejuni*, *Helicobacter pylori*, and *Wolinella succinogenes*. Examples for type C enzymes, which possess two hydrophobic subunits and one heme group, are SQR from mammalian mitochondria and from the proteobacteria *Paracoccus denitrificans* and *Escherichia coli*, and QFR from the nematode *Ascaris suum*. The QFR of *E. coli* is an example for a type D enzyme, which contains two hydrophobic subunits and no heme group. Finally, type E

Figure 1 Electron flow and the generation and utilization of a transmembrane electrochemical potential in aerobic respiration (a) and anaerobic respiration (b). Modified from Lancaster CRD (2003) The role of electrostatics in proton-conducting membrane protein complexes. *FEBS Letters* 545: 52–60, with permission.

enzymes, such as SQRs from the archaea *Acidianus ambivalens* and *Sulfolobus acidocaldarius* and the cyanobacterium *Synechocystis*, and also the methylmenaquinol:fumarate reductases from the epsilon-proteobacteria *C. jejuni* and *W. succinogenes*, also contain no heme, but have two hydrophobic subunits very different from the other four types and more similar to those of heterodisulfide reductase from methanogenic archaea.

SQOR Structure and Function

Overall Description of the Structure

The first available crystal structures of SQORs (Figures 2(b)–2(d)) were those of two prokaryotic QFRs, both since 1999, and one prokaryotic SQR, since 2003. More recently, structures of mitochondrial complex II have become available, those of the porcine and avian enzymes in 2005 and 2006, respectively. The *E. coli* QFR (Figure 2(d)), determined at 3.3-Å resolution, belongs to the type D enzymes and the QFR of *W. succinogenes* (Figure 2(b)), refined initially at 2.2 Å and later at 1.78-Å resolution, is of type B. The structure of the SQR from *E. coli*

(Figure 2(c)) was reported at 2.6-Å resolution, those of the porcine and avian enzymes at resolutions of 2.4 and 1.8 Å, respectively. The latter three structures are very similar. Interestingly, *E. coli* QFR appears to be a monomeric complex of one copy each of the A, B, C, and D subunits, whereas *W. succinogenes* QFR is apparently a homodimer of two sets of A, B, and C subunits, and *E. coli* SQR is a homotrimer of three sets of A, B, C, and D subunits. At least for the B-type enzymes from *W. succinogenes*, *C. jejuni*, and *H. pylori*, it has been derived from analytical gel filtration and analytical ultracentrifugation experiments, that the homodimer is apparently also present in the detergent-solubilized state of the enzyme, implying that it is unlikely to be an artifact of crystallization. However, functionally all three enzymes appear to act as monomers, which is why only the monomeric complexes are shown in Figures 2(b)–2(d).

The Relative Orientations of Soluble and Membrane-Embedded SQOR Subunits

The structures of all three enzymes shown in Figures 2(b)–2(d) can be superimposed on the basis of the Cα positions of the

Figure 2 (a) Classification (A–E) of succinate:quinone oxidoreductases based on their hydrophobic domain and heme content. The hydrophilic subunits A and B are drawn schematically in blue and red, respectively, the hydrophobic subunits C and D in green. Heme groups are symbolized by small rectangles. The directions of the reactions catalyzed by SQR and QFR are indicated by red and blue arrows, respectively. Yellow rectangles symbolize the respective cytoplasmic or inner mitochondrial membrane bilayer. The positive (+) and negative (–) sides of the membrane are indicated. In bacteria, the negative side is the cytoplasm (inside) and the positive side is the periplasm (outside). For mitochondrial systems, these are the mitochondrial matrix and the intermembrane space, respectively. The type of quinone transformed *in vivo* is not necessarily unique for each type of enzyme. The examples given are thermoplasma-quinone (TK), menaquinone (MK), ubiquinone (Q), and caldariella quinone (CQ). (b–d) Three-dimensional structures of *W. succinogenes* QFR, a B-type SQOR ((b) determined by Lancaster et al.), *E. coli* SQR, a C-type SQOR ((c) determined by Yankovskaya et al.), and *E. coli* QFR, a D-type SQOR ((d) determined by Iverson et al.). The Cα traces of the A subunits are shown in blue, those of the B subunits in red, those of the C subunits in pink, and those of the D subunits in green. The atomic structures of the prosthetic groups are superimposed for better visibility. From top to bottom, these are the covalently bound FAD, the [2Fe–2S], the [4Fe–4S], and the [3Fe–4S] iron–sulfur clusters, (and, where present) the proximal and the distal heme b groups. Atomic color-coding is as follows: C, N, O, P, S, and Fe are displayed in yellow, blue, red, light green, green, and orange, respectively. Figures with atomic models were prepared with a version of Molscript (Kraulis PJ (1991) Molscript: A program to produce both detailed and schematic plots of protein structures. *Journal of Applied Crystallography* 24: 946–950.), modified for color ramping (Esnouf RM (1997) An extensively modified version of MolScript that includes greatly enhanced coloring capabilities. *Journal of Molecular Graphics and Modelling* 15: 132–134.), and rendered with the program Raster3D (Merritt EA and Bacon DJ (1997) Raster3D photorealistic molecular graphics. *Methods in Enzymology* 277: 505–524.) (a) Modified from Lancaster CRD (2001) Succinate:quinone oxidoreductases – what can we learn from *Wolinella succinogenes* quinol:fumarate reductase? *FEBS Letters* 504: 133–141, with permission.

conserved hydrophilic subunits A and B. In this superimposition, large parts of the membrane-embedded subunits can be aligned only in the case of *W. succinogenes* QFR and *E. coli* SQR, but not for *E. coli* QFR. However, in an alternate orientation, the transmembrane subunits of *E. coli* QFR and of *W. succinogenes*

QFR can be overlaid in spite of the respective absence and presence of the two heme groups. Consequently, the relative orientations of the hydrophilic subunits and the transmembrane subunits are similar in *W. succinogenes* QFR, *E. coli* SQR, and mitochondrial complex II and different in *E. coli* QFR.

Subunit A, and the Site of Succinate Oxidation/Fumarate Reduction

The flavoprotein or A subunit (64–73 kDa) of all described membrane-bound SQOR complexes contains a flavin adenine dinucleotide (FAD) prosthetic group covalently bound to a conserved His residue as an α -[N ϵ -histidyl]-FAD. The two most important domains of subunit A are the bipartite FAD-binding domain and the 'capping' domain, which is inserted between the two parts of the FAD-binding domain. The capping domain contributes to burying the otherwise solvent-exposed FAD isoalloxazine ring from the protein surface.

The binding site of succinate/fumarate is located between the FAD-binding domain and the capping domain next to the plane of the FAD isoalloxazine ring. The structures and results from site-directed mutagenesis suggest that the *trans* dehydrogenation of succinate to fumarate occurs by the combination of a hydride ion transfer from one succinate methylene group to the N5 position of the FAD and of a proton transfer from the other succinate methylene group to the side chain of a conserved Arg residue of the capping domain (Figure 3). All residues implicated in substrate binding and catalysis are conserved throughout the superfamily of SQORs, so that this reversible mechanism is considered generally relevant for all SQORs. Release of the product could be facilitated by movement of the capping domain away from the dicarboxylate site.

Subunit B, the Iron–Sulfur Protein

Generally, SQORs contain three iron–sulfur clusters, which are exclusively bound by the B subunit of 26–30 kDa. Enzyme types A–D contain one [2Fe–2S]^{2+,1+}, one [4Fe–4S]^{2+,1+}, and one [3Fe–4S]^{1+,0} cluster, whereas an additional [4Fe–4S]^{2+,1+} cluster apparently replaces the [3Fe–4S]^{1+,0} in the type E

enzyme. This subunit consists of two domains, an N-terminal 'plant ferredoxin' domain, in contact with subunit A and binding the [2Fe–2S] iron–sulfur cluster, and a C-terminal 'bacterial ferredoxin' domain, in contact with the hydrophobic subunit(s) and binding the [4Fe–4S] and the [3Fe–4S] iron–sulfur clusters. In general, these iron–sulfur clusters are coordinated by conserved Cys residues, although one of the ligands to the [2Fe–2S] cluster in *E. coli* SQR is an Asp. At the position corresponding to the fourth Cys of the [4Fe–4S] cluster, the [3Fe–4S] cluster contains a Leu (*W. succinogenes* QFR), Ile (*E. coli* SQR), Val (*E. coli* QFR), or Ser (*B. subtilis* SQR), whereas the introduction of a Cys into *E. coli* QFR could replace the native [3Fe–4S] by a [4Fe–4S] cluster, this was not the case for *B. subtilis* SQR.

The Integral Membrane Subunit(s) C (and D) and the Sites of Quinol Oxidation/Quinone Reduction

Type A, C, and D SQOR enzymes contain two hydrophobic polypeptides with three membrane-spanning helices each (numbered I, II, and III and IV, V, and VI, respectively). According to an evolutionary model proposed by Hägerhäll and Hederstedt in 1996, the large single hydrophobic polypeptides of type B SQOR enzymes with five membrane-spanning helices are thought to have evolved from the fusion of the genes for the two small hydrophobic polypeptides with concomitant loss of transmembrane helix III. This view is supported by the structural superpositions discussed above (section IIB). To a varying degree, all transmembrane segments are tilted with respect to the membrane normal.

The planes of both heme molecules bound by *W. succinogenes* QFR are approximately perpendicular to the membrane surface and their interplanar angle is 95°. The His axial ligands to the 'proximal' heme *b_p*, located toward the cytoplasmic

Figure 3 Possible mechanism of succinate oxidation/fumarate reduction. Modified from Lancaster CRD (2001) Succinate:quinone oxidoreductases – what can we learn from *Wolinella succinogenes* quinol:fumarate reductase? *FEBS Letters* 504: 133–141, with permission.

surface of the membrane and, thus, toward the [3Fe–4S] iron–sulfur cluster, are located on transmembrane helices II and V. Also, residues of the two other transmembrane helices I and IV interact with the propionate groups of heme b_p via hydrogen bonds and salt bridges, which underscores the structural importance of the bound heme. The axial ligands to the ‘distal’ heme b_D are located on helices I and IV. The binding of the two heme b molecules by an integral membrane protein four-helix bundle described here is very different from that described for other diheme-binding membrane protein complexes, such as the cytochrome bc_1 complex, where only two transmembrane segments provide two axial heme b ligands each, and also the membrane-bound hydrogenases and formate dehydrogenases, where one transmembrane helix provides two axial His ligands and two others provide one His ligand each. One consequence of this difference is that the distance between the two heme iron centers is distinctly shorter in *W. succinogenes* QFR (15.6 Å) than it is in the mitochondrial cytochrome bc_1 complex (21 Å) and in *E. coli* formate dehydrogenase-N (20.5 Å). The mode of heme binding for the single (proximal) heme of *E. coli* SQR is analogous to that described for heme b_p of *W. succinogenes* QFR.

The sites of quinol oxidation/quinone reduction have been localized in all three enzymes of known three-dimensional structure by a combination of X-ray crystallography, site-directed mutagenesis, functional characterization of resulting variant enzymes, and/or inhibitor-binding studies, respectively. In *E. coli* QFR, the menaquinol oxidation site is located proximally, close to the [3Fe–4S] cluster. In *E. coli* SQR, this position is occupied by the heme b group, but the ubiquinone reduction site is also located proximally, close to the [3Fe–4S] cluster, at an alternate position. In *W. succinogenes* QFR, the menaquinol oxidation site is located distally, close to heme b_D .

Electron and Proton Transfer

Electron Transfer

For the function of QFR, electrons have to be transferred from the quinol-oxidizing site in the membrane to the fumarate-reducing site, protruding into the cytoplasm. Conversely, for the function of SQR, electrons have to be transferred from the succinate oxidation site in subunit A to the quinone reduction site in the membrane. The linear arrangement of the prosthetic groups in the complexes shown in **Figures 2(b)–2(d)**, therefore, provides one straightforward pathway by which electrons could be transferred efficiently between the two sites of catalysis. It has been shown for other electron transfer proteins that physiological electron transfer between prosthetic groups occurs if the edge-to-edge distances relevant for electron transfer are shorter than 14 Å, but not if they are longer than 14 Å. In all three cases, this indicates that physiological electron transfer can occur between the prosthetic groups of one heterotrimeric or heterotetrameric complex, but not between the two (*W. succinogenes* QFR) or three (*E. coli* SQR) complexes in the respective homodimer or homotrimer.

Prior to the determination of the three-dimensional structures, because of its very low midpoint potential ($E_m < -250$ mV), the [4Fe–4S] iron–sulfur cluster had been suggested not to participate in electron transfer. However, the

determined low potential may be an artifact due to anti-cooperative electrostatic interactions between the redox centers. The position of the [4Fe–4S] cluster as revealed in the structures is highly suggestive of its direct role in electron transfer between the [3Fe–4S] cluster and the [2Fe–2S] cluster. Despite this major thermodynamically unfavorable step, the calculated rate of electron transfer is on a microsecond scale, demonstrating that this barrier can easily be overcome by thermal activation as long as the electron transfer chain components are sufficiently close to promote intrinsically rapid electron tunneling.

The positioning of the heme in *E. coli* SQR is apparently puzzling because it does not seem to be required for electron transfer between the catalytic sites. A possible explanation for this also explains why SQR is favored over QFR in *E. coli* when oxygen is present. Under aerobic conditions, reduced *E. coli* QFR produces large amounts of reactive oxygen species (ROS), including superoxide radical (O_2^-) and hydrogen peroxide (H_2O_2), which has been suggested to be caused by electron accumulation around the FAD. In sharp contrast, *E. coli* SQR reacts poorly with molecular oxygen, producing modest amounts of O_2^- and no H_2O_2 . On the basis of their crystal structure, Yankovskaya et al., argue that the heme group in SQR provides an electron sink when the quinone site is not occupied, thus preventing buildup of electrons around the FAD and subsequent ROS generation. However, this electron-sink mechanism is predicted to be less effective for mitochondrial SQRs because heme b has a lower-redox potential than in *E. coli* SQR.

Electron-Coupled Proton Transfer

In addition to the transfer of electrons, two protons are bound at the site of reduction and two protons are liberated at the site of oxidation (see **eqns [1] and [2]**). An overview of the current status of discussion of electron and proton transfer in SQORs is shown in **Figures 4(a) and 4(b)**. In mitochondrial complex II and other C-type enzymes, such as SQR from *P. denitrificans* and *E. coli*, electron transfer from succinate to ubiquinone does not lead to the generation of a transmembrane electrochemical potential Δp , because the protons released by succinate oxidation are on the same side of the membrane as those consumed by quinone reduction (**Figure 4(a)**). Similarly, in *E. coli* QFR, the protons released by proximal quinol oxidation are balanced by the protons consumed by fumarate reduction (**Figure 4(c)**). Succinate oxidation by menaquinone, an endergonic reaction under standard conditions, is catalyzed by a B-type SQOR in Gram-positive bacteria, for example, *B. subtilis*. There is experimental evidence indicating that the menaquinone reduction site in *B. subtilis* SQR is close to the heme b_D in an analogous position to the menaquinol oxidation site of *W. succinogenes* QFR. This arrangement of the catalytic sites of succinate oxidation and menaquinone reduction would allow succinate oxidation by menaquinone in *B. subtilis* to be driven by the electrochemical proton potential (**Figure 4(b)**) and there is indeed experimental evidence that this is the case. This is the analogous reaction to that suggested by the arrangement of the catalytic sites for *W. succinogenes* QFR, but in the opposite direction. Recent experimental results indeed indicate that *B. subtilis* SQR generates a proton potential when

Figure 4 The coupling of electron and proton flow in succinate:quinone oxidoreductases in aerobic (a) and (b) and anaerobic respiration (c) and (d), respectively. Positive and negative sides of the membrane are described for Figure 2. (a, c) Electroneutral reactions as catalyzed by C-type SQR enzymes (a) and D-type *E. coli* QFR (c). (b) Utilization of a transmembrane electrochemical potential Δp as possibly catalyzed by A-type and B-type enzymes. (d) Electroneutral fumarate reduction by B-type QFR enzymes with the compensatory 'E-pathway'. functioning as a QFR. However, the experimental results on intact bacteria, with inverted vesicles or liposomes containing *W. succinogenes* QFR indicate that the oxidation of menaquinol by fumarate as catalyzed by *W. succinogenes* QFR is an electro-neutral process. To reconcile these experimental findings with the arrangement of the catalytic sites in the structure, it has been proposed that transmembrane electron transfer in dihemmic QFRs is tightly coupled to the compensatory, parallel transfer of protons across the membrane, thus balancing the protons released to the periplasm upon menaquinol

oxidation and the protons bound from the cytoplasm upon fumarate reduction (Figure 4(d)). A key residue in this proposed proton transfer pathway is a Glu residue located in the middle of the membrane that is conserved only in dihemmic menaquinol:fumarate reductases, but not in dihemmic succinate:menaquinone reductases. Experimental results proving this 'E-pathway hypothesis' have recently been obtained.

Respiratory Chain Complex IV

H Michel, Max Planck Institute of Biophysics, Frankfurt, Germany

© 2013 Elsevier Inc. All rights reserved.

Glossary

α -Proteobacteria A group of eubacteria containing many well-characterized bacterial species. The evolutionary ancestor of mitochondria is most likely a close relative of the *Rickettsiaceae* which belong to this group of bacteria.

Cyanobacteria Prokaryotes that perform oxygenic photosynthesis. They developed the water-splitting system

converting the atmosphere to an oxidizing one. They are considered to be the evolutionary ancestor of chloroplasts.

Cytochrome *c* A heme-containing hydrophilic protein that functions as an electron carrier in respiration.

Ubiquinol A hydrophobic coenzyme which carries hydrogen atoms in membranes. It can release protons and electrons separately. It forms ubiquinone upon oxidation.

Background

Aerobic, oxygen-consuming respiration is the major means of producing energy in animals, fungi, many yeasts, and bacteria. Oxygen itself is a side product of the oxygenic photosynthesis occurring in plants, algae, and cyanobacteria. These organisms produce reduced coenzymes (nicotinamide adenine dinucleotide phosphate (NADPH), quinols) and adenosine-5'-triphosphate (ATP) in the course of the photosynthetic light reaction. NADPH is used to fix carbon dioxide and to synthesize carbohydrates and other organic compounds during the photosynthetic dark reactions. This organic matter is consumed by heterotrophic organisms. NADH and quinols are formed during the degradation of foodstuff and oxidized in the respiratory chain. In the typical mitochondrial respiratory chain (Figure 1), NADH is oxidized by complex I (NADH dehydrogenase). The electrons are transferred onto ubiquinone; the ubiquinol formed is oxidized by complex III (cytochrome *bc*₁ complex, also called ubiquinol–cytochrome *c* oxidoreductase) which reduces cytochrome *c*. This electron carrier is oxidized again by complex IV (cytochrome *c* oxidase). The latter uses the electrons to reduce oxygen and to form water, thus closing the cycle. Complex II (succinate dehydrogenase) constitutes a parallel entry into the respiratory chain and is also part of the citric acid cycle.

The respiratory chains from aerobic bacteria contain many more membrane–protein complexes and are often branched. They may contain up to four different terminal oxidases reacting with molecular oxygen. The electron-donating substrates for the individual terminal oxidases may be cytochromes of the *c* type, various quinols, or even high-potential iron sulfur proteins. Most of them belong to the family of heme/copper-containing terminal oxidases. The exception is cytochrome *bd*, which is a ubiquinol oxidase and not related to the heme/copper-containing terminal oxidases. Cytochromes *bd* do not pump protons; however, electrons and protons, as in the heme/copper-containing oxidases, enter the active site of this enzyme from opposite sides of the membrane leading to a net translocation of four charges per oxygen molecule consumed.

Astonishingly, the superfamily of the heme/copper-containing terminal oxidases appears to be rather old. Family members are found in bacteria, as well as in archaea. They

splitting into these lineages during evolution predates the conversion of the atmosphere from a reducing one to an oxidizing one, which dates back to ~2 billion years, when cyanobacteria developed the water-splitting, oxygen-releasing photosystem II. It turned out that the nitric oxide reductase (nitrogen monoxide reductase, NO reductase) is closely related to the heme/copper-containing terminal oxidases. An iron atom in the NO reductases replaces a copper atom which is a part of the active site in the heme/copper-containing terminal oxidases. NO reductases appear to be unable to pump protons. The original task of both the heme/copper-containing terminal oxidases (which are *OO* reductases) and the NO reductases might have been detoxification. Molecular oxygen, being toxic for the organisms living under the reducing atmosphere, might have been created by photolysis of water by ultraviolet light and had to be destroyed.

Prosthetic Groups

The heme/copper-containing terminal oxidases minimally contain two heme groups and one copper atom as prosthetic groups. One of the heme groups is a high-spin heme. A copper atom, called Cu_B, is found in ~5Å distance. Cu_B and the high-spin heme form the so-called 'binuclear center'. During turnover, molecular oxygen is bound to the central iron atom of the high-spin heme between the heme and Cu_B and reduced there during the catalytic cycle of the enzyme. The second heme is a low-spin heme and acts as an intermediate electron carrier.

The optical absorbance spectra have been the signature for the cytochrome *c* oxidases. In the mitochondrial cytochrome *c* oxidases both hemes are of the A type (see Figure 2), which give rise to characteristic absorbance maxima at around 600 nm. The high-spin heme of the active site is called 'heme *a*₃', the low-spin one heme *a*. The term cytochrome *aa*₃ was used for the terminal oxidase of mitochondria. In many bacteria, the low-spin heme is a heme B, giving rise to a terminal oxidase of the *ba*₃ type. One ubiquinol oxidase of *Escherichia coli* contains heme O as the high-spin heme; therefore, it is also called 'cytochrome *bo*' or '*bo*₃'.

Cytochrome *c* oxidases contain another copper center, which is called Cu_A. It is actually formed by two copper atoms, which share one electron upon reduction. During

Figure 1 The mitochondrial respiratory chain. The five complexes of the respiratory chain are presented with their known structures in a functional context. The atomic structure of complex I or NADH dehydrogenase (left) is not known, but its shape has been determined by electron microscopy. It reduces ubiquinone to ubiquinol and pumps protons. Complex II (succinate dehydrogenase) is represented by a chain model. It also produces ubiquinol (QH₂). Ubiquinol is oxidized by complex III (cytochrome *bc*₁ complex). The cytochrome *bc*₁ complex releases protons at the outside and uses a quinone cycle to translocate additional protons across the membrane. The cytochrome *bc*₁ complex from yeast is shown. It reduces cytochrome *c*, which is oxidized by cytochrome *c* oxidase. The bacterial cytochrome *c* oxidase from *Paracoccus denitrificans* is shown. Cytochrome *c* oxidase pumps protons. The pumped protons flow back via the membrane part of complex V (ATP synthase). The backflow leads to a rotation of a subunit in the extra-membranous part of the ATP synthase, which is coupled to the synthesis of ATP. Proton flows are indicated by the red arrows. Figure drawn by P. Lastrico and E. Olkhova.

Figure 2 Chemical structures of the noncovalently bound hemes found in terminal oxidases. The structures of heme A, heme B, and heme O (from left to right) are shown.

turnover of the enzyme, Cu_A receives the electron from cytochrome *c* and transfers it to the low-spin heme. Ubiquinol oxidases do not possess this Cu_A center. Several terminal oxidases also contain a covalently bound cytochrome *c*. Depending on the nature of the other hemes these enzymes are called *caa*₃, or *cbo*, or *cbb*₃ oxidases. The terminal oxidases of the *cbb*₃ type operate at rather low-oxygen concentrations and, for example, are required for the nitrogen fixation in *Rhizobia* in order to keep the oxygen levels very low.

Cytochrome *c* oxidases also contain a magnesium or manganese atom close to the periplasmic (intermembrane) face of the enzyme. It is missing in the ubiquinol oxidases and does not appear to be involved in electron transfer.

Protein Composition

The mitochondrial cytochrome *c* oxidases possess a core consisting of three protein subunits. These subunits are encoded by the mitochondrial genome. Subunit I is the largest subunit and possesses between 500 and 600 amino acid residues. It binds heme *a* as well as the heme *a*₃-Cu_B binuclear center and is the major catalytic subunit. Subunit II provides the binding site for the Cu_A center and is anchored to the membrane by two N-terminal membrane-spanning helices. Subunit III possesses seven membrane-spanning helices but no prosthetic groups. Its function is unknown; it is not required for the catalytic activity. If its gene is deleted in bacteria, an active two-subunit enzyme is still found, albeit at a reduced level. If subunit III is removed, the enzyme becomes rather unstable under turnover conditions.

The mitochondrial cytochrome *c* oxidases contain up to eight additional smaller subunits, which are encoded by the nuclear genome. For some of the subunits, organ-specific subtypes exist; for example, there are liver and heart types of the so-called subunit VIa in the mammalian cytochrome *c* oxidase. It has been suggested that the presence of the liver or heart type determines the efficiency of proton pumping, and that only two protons per oxygen molecule are pumped by cytochrome *c* oxidase in liver, but four in heart. Subunit VIa also seems to be responsible for the dimer formation of cytochrome *c* oxidase from bovine heart mitochondria.

The bacterial cytochrome *c* oxidases of known structure contain one additional small protein subunit, called 'subunit IV'. It has no counterpart in the mitochondrial enzyme and its function is not known.

X-Ray Crystal Structures of Cytochrome *c* Oxidases and Other Terminal Oxidases

Protein Structure

Until now atomic structures, determined by X-ray crystallography, have been presented for the cytochrome *c* oxidases from the soil bacterium *Paracoccus denitrificans*, from the purple photosynthetic bacterium *Rhodobacter sphaeroides*, and from bovine heart mitochondria. These are rather typical closely related enzymes. Both *Paracoccus* and *Rhodobacter* are grouped within the α -proteobacteria, and the symbiotic ancestor of the mitochondria belonged to this group. In addition, the

structure of the aberrant *ba*₃-type cytochrome *c* oxidase (e.g., it does not possess a homolog of subunit III) from the bacterium *Thermus thermophilus*, and that of the ubiquinol oxidase (cytochrome *bo*₃) from *E. coli* have been determined.

In the cytochrome *c* oxidases the subunits I, II, and III form the core, which, viewed parallel to the membrane, has a trapezoidal shape, when seen from above it looks oval. The length of the trapezoid is about 90 Å, its height is 55 Å. It comprises 21 membrane-spanning helical segments. The globular polar domain of subunit II is attached to the narrow, periplasmic (intermembrane, respectively) side of the trapezoid (see Figures 1 and 3). Subunit I contains 12 membrane-spanning helices which are arranged in a threefold symmetric manner. In this kind of arrangement, three pores are formed. One contains the heme *a* with two histidine residues as axial iron ligands, another heme *a*₃ with one axial histidine ligand and Cu_B, and the third one is blocked by aromatic residues. Subunit II contains two N-terminal membrane-anchoring transmembrane helices. The globular domain contains a 10-stranded β -barrel similar to the copper proteins plastocyanin and azurin. The copper-binding site is in the same position, but to subunit II two copper atoms instead of one are bound. Subunit III possesses seven transmembrane helices. They form two bundles, one of five, the other of two transmembrane helices. Between them a V-shaped cleft exists, which is partially filled by lipid molecules. In the cleft at the center of the membrane, an entrance to a hydrophobic channel can be seen which leads to the active site. It has been proposed that this channel is a diffusion channel for oxygen because it leads to the active site, and because the solubility of oxygen in the hydrophobic center of the membrane is considerably higher than in the aqueous phase. Subunit III of the ubiquinol oxidase (cytochrome *bo*₃) from *E. coli* consists of five transmembrane helices only. The loss is compensated by the addition of two transmembrane helices to the 12 of subunit I.

Arrangement of the Prosthetic Groups

Cu_A receives an electron from cytochrome *c* at the periplasmic (intermembrane) surface of the membrane. Tryptophan 121 (*Paracoccus* numbering) appears to play an important role in the electron transfer. From Cu_A the electron is transferred to heme *a*, the distance of the lower Cu atom to the iron atom of heme *a* is ~20 Å. Heme *a*₃ lies in the membrane in the same height, so that electron transfer from heme *a* to heme *a*₃ occurs parallel to the membrane. The center-to-center distance of both hemes is 13–14 Å. The propionate side chains of both heme groups are oriented toward the external (periplasmic or intermembrane) side. Their charges are partially compensated by the formation of ion pairs with two arginine residues.

Cu_B is ~5 Å away from the heme *a*₃ iron, so that a very rapid electron transfer between heme *a*₃ and Cu_B has to be expected. It is a general problem in cytochrome *c* oxidase research that Cu_B is silent and there is no spectroscopic technique available which allows determining the redox state of Cu_B. Cu_B possesses three histidine ligands. One of them is covalently linked to a nearby tyrosine. The existence of a covalent histidine-tyrosine cross-link was unknown prior to the X-ray crystallographic structure determinations.

Figure 3 Cytochrome *c* oxidase in a bilayer membrane. The four subunits containing cytochrome *c* oxidase from *Paracoccus denitrificans* are shown together with its substrate cytochrome *c* (purple, top). Helices are represented as columns, β -strands as ribbons with arrows. Green: subunit I; dark blue: subunit II; iceblue: subunit III; gray: subunit IV; heme *a* is shown in orange, heme *a*₃ in red, Cu_B in yellow, and Cu_A in mauve. The lipid bilayer is represented in gray as atomic model. Figure prepared by E. Olkhova using the program VMD.

Proton Transfer Pathways

The structural knowledge combined with the results of previous site-directed mutagenesis experiments lead to the identification of two proton transfer pathways. One, called the K-pathway because of the existence of an essential lysine residue as a component of this pathway, leads straight from the cytoplasmic (matrix) surface into the binuclear site. The cross-linked tyrosine is a part of it. Mutation of the essential lysine residue to other residues prevents the initial reductions of the binuclear site during the catalytic cycle.

A second proton transfer pathway has been called the D-pathway because an aspartic residue at the protein surface is a part of it. A change of this aspartate residue to an asparagine still allows a (reduced) turnover of the enzyme, but proton pumping is abolished. The D-pathway is wider than the K-pathway, and many water molecules are involved. It leads straight up first, then changes direction at a water-filled cavity, which leads to a glutamate residue (E278 in *Paracoccus* numbering). The further pathway is unclear.

There must be a possibility for proton transfer to the active site, because the reaction cycle can be started from an artificially fully reduced enzyme in K-pathway mutants, proceeds quite normally, and water is formed in the active site. Proton transfer using a temporarily established chain of water molecules is a possibility. Alternatively, pumped protons can be transferred to the heme propionates and stored there in some parts of the catalytic cycle.

The existence of a third pathway, called H-pathway, has been suggested for the bovine heart mitochondrial cytochrome *c* oxidase. However, there is no evidence for it on the basis of mutagenesis experiments in bacterial enzymes and the proposal has met with a lot of skepticism.

The Catalytic Cycle and Proton Pumping

The catalytic cycle starts with a fully oxidized enzyme (O-state). All four prosthetic groups (Cu_A, heme *a*, heme *a*₃, and Cu_B) are oxidized. In cytochrome *c* oxidases an electron is first transferred from cytochrome *c* to Cu_A, and then to heme *a* with a time constant of 20–50 μ s. The published values for the electron transfer to heme *a*₃ from heme *a* vary greatly and most likely this electron transfer requires proton uptake via the K-pathway first. Most likely in this E-state, the single electron equilibrates over all prosthetic groups. A second electron has to be provided by cytochrome *c*. When the binuclear site is doubly reduced, an oxygen molecule can be bound to the iron atom of heme *a*₃; thus the oxygenated form, called compound A, corresponding, for example, to oxygenated myoglobin, is formed. This reacts to an intermediate state called P, which is characterized by an absorption maximum at 607 nm. P stands for peroxy because the original (incorrect) belief was that this form contains a peroxide dianion. After the input of a third electron into the enzyme a state absorbing visible light at

Figure 4 Catalytic cycles of cytochrome *c* oxidase. Classical, now obsolete, cycle with only four states. The P-state erroneously has a peroxide anion bound to the heme *a*₃-iron; two protons are pumped during the P- to F-, and during the F- to O-transitions under consumption of two protons each. It is clear now, that only one proton is consumed during each transition. (a) Adaptation of the classical cycle to recent findings. Two protons are taken up already during the initial two-electron reduction of the enzyme, and two protons are pumped in this phase (under turnover conditions). The P_M-state contains an oxoferryl-iron, a tyrosine radical, and a hydroxide in the binuclear center, only one proton is pumped during the P- to F-, and during the F- to O-transitions. (b) A recent cycle with two P- and two F-states. The protonations of the hydroxides in the binuclear sites of the P-states leads to proton pumping, each electron uptake is accompanied by a charge-compensating proton uptake. Tyrosine radicals are present in the two-electron reduced states, and tyrosines in the three-electron reduced states. One proton is pumped during the second reduction step, which could now be experimentally demonstrated. One electron is pumped during the F- to O-transition as a result of the protonation of the oxo-group at the heme *a*₃ iron (c).

580 nm is formed. This was believed to be the oxoferryl state and called F. After the fourth reduction step, the iron-bound oxygen atom was thought to be converted to a second water molecule under consumption of two protons and the O-state is formed again. Such a simple catalytic cycle is presented in Figure 4(a).

In recent years, much of the accepted knowledge had to be revised. First, it is clear now that there are two P- and F-states each, one each in the two-electron reduced enzyme, and one each in the three-electron reduced enzyme. It cannot be excluded that all of them are part of the catalytic cycle (Figure 4). Second, it has been convincingly demonstrated by

resonance Raman spectroscopy and chemical experiments that in the P-state the O=O double bond is already broken and that an oxoferryl state already exists. This finding causes the problem that four electrons are required to split the O=O double bond, but only three (two from the Fe^{II} to Fe^{IV} transition upon formation of the oxoferryl state, and one from Cu_B) are available from the prosthetic group. Although definite proof could not be presented yet, it is the general belief that the fourth electron (and a proton) is provided by the cross-linked tyrosine, which becomes a neutral tyrosine radical. The existence of the cross-link, which most likely is a side product formed by a tyrosine radical in one of the first turnovers, has to be considered as a hint for the occurrence of a tyrosine radical. Also, most likely, a hydroxide as a Cu_B-ligand is generated, and may cause the difference of the optical absorbance spectra between the P- and the F-states. The F-state in the three-electron reduced enzyme is most likely to contain water instead of the hydroxide, and the tyrosine radical has become a neutral tyrosine.

The question, which of the electron transfer steps are coupled to proton pumping, is currently a matter of intense debate. The already generally accepted proposal that only the P- to F-, and F- to O-transitions are linked to proton pumping with two protons pumped each, could not be maintained. There is good evidence that one proton is pumped upon the input of the second electron into the oxidized enzyme in the absence of oxygen, and it has also been proposed that under turnover conditions already the first reduction step is connected to proton pumping. For a final answer, further experiments are required. It is a general problem in cytochrome *c* oxidase research that many kinetic experiments are started from a fully reduced enzyme (all four prosthetic groups are artificially reduced). However, this state is not part of the catalytic cycle and the value of the conclusions drawn is limited. As long as it is unknown, when proton pumping occurs in the catalytic cycle, it is very difficult to find out the mechanism of proton pumping. A rather general mechanism of proton pumping, which has found many supporters, is based on the charge-compensation principle. This principle states that each electron transfer into the membrane to heme a is

charge-compensated by uptake of one proton from the opposite side of the membrane and not consumed in water formation. This proton is supposed to be electrostatically repelled and thus pumped by those protons, which are later taken up and consumed in water formation. The mechanism requires storage of the charge-compensating protons in a way that they cannot be used for water formation.

It is evident that still many experiments are required before the mechanism of proton pumping by cytochrome *c* oxidases can be considered to be known.

Glossary

Apoptosis Programmed cell death.

Cell cycle The complete sequence of events needed for the production of a new daughter cell. A mitotic cell cycle has two major landmarks, S-phase and mitosis, which are separated by two gap phases, G1 (the period before DNA synthesis) and G2 (the period between the S- and M-phases).

Cell proliferation The overall increase in cell number that occurs when the rate of cell division is greater than the rate of cell death.

Compensation A change in function that allows one type of gene product to perform a function that is normally carried out by another type of gene product.

Redundancy The situation that occurs when two or more genes have a similar function and either gene is sufficient for a biological process.

The retinoblastoma protein (pRB) is the product of the retinoblastoma tumor susceptibility gene (*RB1*). The gene takes its name from the discovery that mutation of both copies of *RB1* is the critical rate-limiting event in the development of retinoblastoma, a rare form of cancer that affects very young children. Mutation of *RB1* is also found in a variety of cancers and pRB is thought to be functionally inactivated in most tumor cells. pRB is a nuclear protein, present in most cell types, which functions as a general negative regulator of cell proliferation. It is a member of a family of proteins (the pRB family) that have overlapping functions and are regulated by cyclin-dependent kinases. pRB is generally thought to function by controlling gene expression, and its best-known target is the transcription factor E2 promoter-binding factor (E2F).

The pRB Family of Proteins

pRB-related proteins are conserved in plants and animals. Mammalian cells contain three pRB-family members (pRB, p107, and p130) that share a similar domain structure and a low, but significant, degree of primary sequence homology. All three proteins contain a conserved pocket domain that provides binding sites for E2F proteins, and complexes that repress transcription. In addition, pRB, p107, and p130 contain many sites for phosphorylation by cyclin-dependent kinases (cdks). Although pRB, p107, and p130 are currently studied for their roles in the control of cell proliferation, these proteins were first discovered as cellular targets of the viral oncoprotein adenovirus E1A. The binding sites for pRB, p107, and p130 map to the regions of E1A that are needed for its oncogenic properties. Similar sequences are also present in the E7 proteins of human papilloma viruses and large T antigens of several polyoma viruses. In each case, genetic studies show that the ability of the viral proteins to bind to pRB/p107/p130 allows them to interfere with control of cell proliferation. The viruses are thought to use these interactions to create a cellular environment that is favorable for viral replication.

The RB Tumor Suppressor

RB1 was the first tumor suppressor gene to be identified and it is often described as a prototype for this class of cancer-related genes. Unlike oncogenes, whose activation promotes tumorigenesis, it is the inactivation of tumor suppressor genes that is linked to the development of cancer.

Individuals inheriting a mutant allele of *RB1* are strongly predisposed to develop retinoblastoma within the first 2 years of life. Patients, successfully treated for eye cancer, often develop osteosarcoma in later life. Inactivation of *RB1* appears to be essential for the development of both familial and sporadic retinoblastoma, and also occurs in many osteosarcomas. *RB1* mutation is common in small-cell lung cancers and has also been found in other tumors, including bladder, prostate, and breast carcinomas. pRB is broadly expressed and thought to control the proliferation of most cell types. Although *RB1* is mutated in only a subset of tumors, pRB is thought to be functionally compromised in most tumor cells by alternative mutations in the Rb pathway (see below).

Precisely why people who inherit a mutant allele of *RB1* are predisposed to certain types of cancer is still largely unclear. Part of the explanation may stem from the fact that pRB has a distinct pattern of expression: it is broadly expressed but its levels are strongly upregulated in specific cell types, particularly during cell-cycle exit. As described below, a second reason is that pRB shares overlapping functions with the related proteins p107 and p130. p130 is most highly expressed in differentiated cells, whereas p107 is highly expressed in populations of proliferating cells. The ability of p107 and p130 to compensate for the loss of pRB varies in different cellular contexts and also varies between species. This was illustrated by the unexpected finding that mice carrying a mutant allele of the *Rb* gene do not develop retinoblastoma but develop pituitary and thyroid tumors instead. The combined mutation of *Rb* and either of the related *p107* or *p130* genes allows tumors to develop in the murine retina. This suggests that p107 and p130 are able to compensate for the absence of pRB in the developing mouse retina in a way that is different from humans.

A third reason why pRB inactivation has tissue-specific consequences is that, in addition to its apparently universal role in E2F regulation (see below), pRB also interacts with several cell-type-specific factors. For example, pRB interacts with the osteoblast transcription factor CBFA1/RUNX2 to promote the expression of bone-specific genes, and this role may explain why pRB is important for suppression of osteosarcoma. Studies in mice suggest that the presence of pRB facilitates cell-cycle exit, promotes the expression of markers of differentiation, and helps to maintain the quiescent state. In some progenitors, the presence of pRB also helps cells choose between different cell fates.

The Cellular Function of pRB

Since it is the inactivation of pRB that is linked to the development of cancer, the function of pRB is most commonly viewed through the prism of the cellular changes that occur when pRB is removed. pRB-deficient cells are slightly smaller than wild-type cells and have defective cell-cycle control. In tissue culture assays, *Rb*^{-/-} cells are generally less responsive to signals that cause wild-type cells to stop proliferating, and they are more easily driven from quiescence into the cell cycle. *Rb*^{-/-} cells fail to arrest in G1, or in S-phase, in response to DNA damage. pRB-deficient cells also show a reduced sensitivity to p16^{INK4}-induced cell-cycle arrest and ras-induced senescence. Studies in primary cultures of human and mouse cells have revealed that *Rb*^{-/-} cells are genetically unstable. *Rb*^{-/-} cells have chromosome defects; they display high levels of chromosome instability and are prone to polyploidy or aneuploidy. Cells lacking pRB have an altered sensitivity to apoptosis, a change that involves both cell autonomous and nonautonomous changes and results from both the misexpression of apoptotic regulators and defects in cell-cycle arrest.

Analysis of the murine pRB-family has revealed an extensive degree of redundancy and compensation between family members. Each of the pRB family members has been inactivated in the mouse by homologous recombination. *Rb*-deficient mice die during embryogenesis, displaying elevated levels of apoptosis, inappropriate cell proliferation, and developmental defects in several tissues. Animals lacking two pRB family members are more severely affected than the single knockouts, and the inactivation of all three family members renders cells unresponsive to most types of G1 control. Triple knockout cells differentiate poorly, are readily immortalized, and easily transformed. Remarkably and unexpectedly, the early lethality of *Rb*^{-/-} animals has been shown to be largely an indirect consequence of a placental defect. When pRB is expressed specifically in the placenta, the rescue of placental function allows *Rb*-mutant embryos to survive close to birth. Although these mutant animals have defects in cell-cycle control, and in skeletal muscle development, the development of these animals is surprisingly normal. Experiments in tissue culture using cells derived from the knockout animals have shown that the sudden removal of pRB causes more severe cell-cycle control defects than those seen in cells derived from *Rb*^{-/-} animals. This difference is due, at least in part, to an upregulation of *p107* expression that occurs following the sustained absence of pRB and appears to allow p107 to compensate for the loss of pRB.

pRB and Cell-Cycle Regulation

pRB is a critical component of the cell-cycle control machinery, being a regulator of the cell cycle and, in turn, being regulated during cell-cycle progression. pRB is a long-lived protein (half-life > 16 h) and its activity is controlled by phosphorylation. When normal cells proliferate, pRB is inactivated by cdks, the kinases that drive progression through the phases of the cell division cycle. When cells cease to proliferate, the loss of cdk activity allows pRB to accumulate in its active form. Inactivation of pRB is not achieved by the phosphorylation of a single site but by the accumulation of phosphorylated residues at multiple sites that are scattered throughout the protein. A cluster of phosphorylation sites is found in the C-terminal fragments of pRB, p107, and p130 and the accumulation of negative charge in this domain is believed to drive a large conformation shift that regulates interactions with an assortment of cellular proteins. In a similar manner, phosphorylation of the pocket and amino-terminal domains is thought to promote the functional inactivation of pRB.

When quiescent cells are driven into the cell cycle, pRB is sequentially phosphorylated by multiple kinases. Cyclin D/cdk4 is believed to be the first kinase to act on pRB with cyclin E/cdk2, and perhaps cyclin A-dependent kinases completing the process. Phosphorylation of pRB causes it to migrate slowly on sodium dodecyl sulfate-polyacrylamide gel electrophoresis (SDS-PAGE) gels. This mobility shift is often used as an indicator of pRB activity, but it is an unreliable measure; pRB inactivation involves the cumulative effects of multiple phosphorylation events, and some modifications have no effects on the migration of the protein, whereas changes at others sites have a major effect.

Microinjection experiments on cultures of synchronized cells first showed that the ability of pRB to prevent cells from entering S-phase is restricted to a window within G1 phase of the cell cycle. Once cells progressed beyond a point in G1, ~2–4 h prior to S-phase, the introduction of pRB had no effect. The loss of a pRB-induced arrest correlates with the accumulation of cdk activity and corresponds approximately to the restriction point, a point in G1 where cells become irreversibly committed to progress through a complete cell cycle. pRB that has been phosphorylated by cdks *in vitro* is unable to arrest cells in G1. pRB is abruptly dephosphorylated at metaphase of mitosis and re-associates with chromatin.

Phosphorylation is not the only type of modification of pRB to be described. Under specific conditions, pRB can also be acetylated, methylated, ubiquitinated, or sumoylated, and these posttranslational modifications have been proposed to modulate specific aspects of pRB function. Although the details have yet to be fully elucidated, these additional modifications are thought to influence both the level of pRB phosphorylation and the types of cellular proteins that physically interact with pRB.

The Rb Pathway

pRB is a component of a critical regulatory pathway that is functionally inactivated in most tumor cells. This pathway comprises pRB, cyclin D/cdk4 (the kinase that phosphorylates

pRB in G1), and p16^{INK4} (a cdk inhibitor that antagonizes cyclin D/cdk4 activity and is induced in response to certain cellular stresses). Initial experiments showed that the overexpression of cyclinD/cdk4 phosphorylates pRB and prevents it from arresting the cell cycle. In addition, cells lacking pRB are largely insensitive to p16^{INK4}-induced cell-cycle arrest. Subsequent studies have revealed that changes in the levels of either the INK4 family (p16^{INK4A}, p15^{INK4B}, p18^{INK4C}, and p19^{INK4D}) or Cip/Kip families of cdk inhibitor proteins (p27^{kip1}, p21^{cip1}, and p57^{kip1}) can also have profound effects on the activity of pRB.

The p16^{INK4}/cyclin D/cdk4/pRB pathway is disrupted in a variety of ways in tumor cells. Retinoblastoma cells, for example, contain mutations in *RB1*. Many cervical cancers, on the other hand, express HPV E7 proteins that bind and inactivate all three of the pRB family members. Other cells contain lesions that elevate the activity of the cyclin D/cdk4 kinase (overexpression of cyclin D1, loss of the p16^{INK4} cdk inhibitor, or mutations of cdk4 that are resistant to p16^{INK4}). Although most tumor cells contain one of these changes, these lesions primarily occur in a mutually exclusive manner. This may mean that there is no further selection for changes in this group of genes once the p16^{INK4}/cyclin D/cdk4/pRB pathway is disrupted. However, it is also true that several types of tumors are associated with specific types of mutations (e.g., pRB mutations are the only types of lesions in this pathway found in retinoblastoma, while most breast cancers contain elevated levels of cyclin D1); hence, the relative importance of individual components of the pathway varies greatly between cell types.

Molecular Functions of pRB

More than 160 different cellular proteins have been reported to associate with pRB and many of these have been proposed to contribute to its tumor-suppressing properties. Most of these pRB-associated proteins are transcription factors and, although the list is diverse, in general pRB has been proposed to inhibit the activity of factors that are needed for cell proliferation, but to augment the activity of factors that promote cell differentiation.

The best-characterized property of pRB is its ability to repress E2F-dependent transcription. The E2F transcription factor allows the periodic expression of a large number of proliferation-related genes to be tightly coupled with cell-cycle position. E2F controls the expression of an extensive network of genes that includes essential components of the DNA synthesis machinery and proteins needed for cell-cycle progression, mitosis, checkpoint responses, and regulators of apoptosis. pRB blocks cell proliferation, at least in part, by blocking the expression of E2F-regulated genes.

E2F complexes are strong repressors of transcription in quiescent cells and during G1 phase of the cell cycle. As cells progress toward S-phase, these repressor complexes are disrupted and replaced by E2F activator complexes in a cdk-regulated process. All three pRB-family members associate with E2F proteins. In wild-type cells, p107 and p130 associate primarily with E2F4 and E2F5 and are components of E2F repressor complexes. In these complexes, the pRB-family members act as adapter proteins: binding to E2F with one surface

and to chromatin remodeling proteins through a second binding site (the LXCXE-binding cleft). In doing so, they allow a variety of enzymatic activities to be recruited to E2F-regulated promoters. In a similar manner, pRB also interacts with E2F4 or E2F5 and has the potential to recruit repressor complexes to DNA. In addition, pRB has the important ability to regulate E2F1, E2F2, and E2F3, the activator forms of E2F. pRB binds to an element that is buried within the transcriptional activation domain of the E2Fs, preventing them from activating transcription. This inactivation of the activator E2Fs is one of the first steps in the silencing of proliferation genes during cell-cycle exit. Biochemical studies have also shown that pRB that is recruited to DNA by its association with E2F is also able to prevent adjacent DNA-bound transcription factors from interacting with the basal transcription machinery.

Chromatin immuno-precipitation (ChIP) experiments have provided a great deal of information about the binding of E2F and pRB-family members to E2F-regulated promoters during cell proliferation and cell-cycle exit. Surprisingly, p107 and p130 are the pRB-family members that are most easily detected at most E2F targets in most cell types. While some studies have found pRB at E2F-regulated promoters in cultures of proliferating cells, others show that pRB is preferentially recruited to E2F targets in response to specific signals, such as p16-induced cell-cycle arrest, DNA damage, or following ras-induced senescence. Under these circumstances, pRB is thought to recruit histone deacetylase and/or histone methylase activities to DNA. These complexes repress transcription through modification of histone tails, changing the local chromatin structure to a form that is nonconductive to gene expression.

ChIP studies suggest that there is not a single group of promoters that is targeted by pRB, p107, and p130, nor is there a single mechanism of repression. Many different promoters can be repressed by pRB, p107, or p130, and the types of repressor complexes that are operative at these promoters can vary depending in part on whether the cells are proliferating, quiescent, undergoing senescence, differentiating, or responding to DNA damage. Currently, it seems unlikely that there is a single form of pRB-mediated transcriptional regulation. Instead, pRB-family members seem to be versatile proteins that are capable of recruiting several types of repressor activities to chromatin. A key goal for future studies will be to identify the underlying rules that can explain which types of repressor complexes are recruited to individual promoters and when the presence of the different complexes becomes functionally significant.

Although E2F is the best-known target, pRB's physical interactions with other cell-cycle regulators also help to promote normal cell-cycle control. pRB has been detected at origins of replication and reported to relocalize near to replication origins following DNA damage. In addition to repressing E2F-dependent transcription, pRB also promotes cell-cycle exit by increasing the levels of p27^{kip1}. pRB stabilizes p27^{kip1} by its binding to S-phase kinase-associated protein 2 (Skp2/p45) and preventing the SCF^{Skp2} ubiquitin ligase from targeting p27. This regulation is enhanced by pRB's ability to associate with the ubiquitin ligase anaphase-promoting complex and its activator cadherin-1/E-cadherin (APC-Cdh1) and to promote APC-Cdh1-mediated turnover of Skp2.

Genetic interactions between *Rb* and *E2F* genes have been demonstrated in multiple experimental systems and in species

as diverse as mice and fruit flies. Nevertheless, it is important to remember that pRB has many binding partners and precisely how much of pRB's functions in development and tumor suppression are mediated through its interaction with E2F is uncertain. The developmental defects of *Rb*^{-/-} mice can be partly suppressed by mutations in E2F genes (*E2f1* and *E2f3*), but rescue can also be seen with mutant alleles of the differentiation regulator, *Id2*, and the apoptotic regulators *Apaf1* and procaspase3 (*casp3*). In each case, individual mutant alleles give only a partial rescue of the *Rb*^{-/-} phenotype, suggesting that the *Rb*^{-/-} mutant phenotype is too complex to be corrected by manipulating a single pathway.

One of the ultimate goals of pRB research is to find ways to selectively kill *Rb*^{-/-} tumor cells. Excitingly, several mutations have been shown to reduce tumor phenotypes of *Rb*^{+/-} mice. These include mutant alleles of *E2f1*, *E2f3*, *E2f4*, *K-ras*, and *Skp2*. One of the most striking of these interactions has been observed with *Skp2*. *Skp2* is the product of an E2F-regulated gene and is aberrantly overexpressed in many human cancers. Studies in mice show that *Skp2* is not generally required for tumorigenesis or for animal development; nevertheless, the inactivation of *Skp2* suppresses tumorigenesis in the pituitary by inducing apoptosis in *Rb*^{-/-} cells. Additional studies in other model organisms show that there may be several additional pathways that can be targeted in a way that is synthetically lethal with the inactivation of pRB. However, studies of pRB function suffer from the general caveat that the precise role of pRB is heavily dependent on the context in which it is studied, and many of the genetic interactions reported for *Rb* are cell-type specific.

Glossary

Retinoic acid The derivative of the fat-soluble vitamin A that is active in the regulation of gene expression by activating nuclear retinoic acid receptors.

Transcription The process by which RNA polymerase II is recruited to the promoter of a gene and

enzymatically copies the base sequence of a gene into an RNA transcript.

Transcription factor A protein or collection of proteins that are involved in altering the efficiency of RNA polymerase II activity in transcribing a gene.

Retinoic acid receptors (RARs) are nuclear transcription factors that, once activated by retinoic acid (RA), regulate the expression of RA target genes, leading to changes in cell differentiation, cell proliferation, and apoptosis. The discovery of the first RAR in 1987 defined for the first time the mechanism of action of vitamin A outside of the visual cycle. Three RAR subtypes have been identified in the vertebrate genome and have been named RAR α , RAR β , and RAR γ .

RA and RA Signaling

RA is a signaling molecule derived from vitamin A (retinol) that is essential for normal embryonic development and health in the adult. RA is produced in a two-step enzymatic process involving the alcohol dehydrogenase-mediated conversion of retinol to retinaldehyde and, in a subsequent retinaldehyde dehydrogenase-catalyzed step, to RA. RA signaling is mediated by RARs.

RARs belong to the superfamily of nuclear hormone receptors and bear conserved structural similarities to other members of this family, including estrogen and androgen receptors, glucocorticoid receptor, thyroid hormone receptor, and vitamin D receptor. In general, members of this family can be distinguished by the linear arrangement of six more or less conserved functional domains designated A through F. Key functional domains of RARs include the RA-binding domain, the DNA-binding domain, and two separate transcription activation domains (see Figure 1). Although the DNA- and RA-binding domains of the RARs are similar between subtypes, the transcription activation domains vary considerably, possibly reflecting target gene-specific interactions. Several regions within RAR domains mediate specific interactions with retinoid X receptor subtypes (RXR α , RXR β , or RXR γ), forming an obligatory heterodimeric partnership required for activation of RA target genes. RAR/RXR heterodimers bind to specific DNA elements called retinoic acid response elements (RAREs) usually found in the promoters of such genes. The unique expression patterns of each RAR subtype in the embryo and the adult also support the specific functional role that each of the RARs fulfills. Murine knockout studies have revealed that although there is functional redundancy between RARs, each receptor is essential for normal physiology.

RAR Structure and Function

RARs share structural similarities with other members of the nuclear receptor family. The key functional domains of RARs include the RA-binding domain, the DNA-binding domain, transcriptional activation domains, and amino acid sequence motifs that are necessary for interactions between RARs and other transcription factors, including RXRs. RARs form heterodimeric complexes with RXRs in order to regulate gene expression.

DNA-Binding Domain

The hallmark of all nuclear receptors is the DNA-binding domain (domain C), which comprises a highly conserved, 66–68-amino-acid stretch encoding two zinc-binding fingers labeled C1 and C2. The DNA-binding domain of the RARs is 66 amino acids in length, and its structure has been determined by X-ray crystallographic studies. The two zinc fingers fold into a globular domain such that residues of the first zinc-binding finger (C1) make specific contacts with DNA through interactions between three conserved amino acid residues (P-box) with specific base residues in the major groove of the DNA double helix. The second zinc finger (C2) is more basic in nature, making contacts with the negatively charged phosphate backbone of DNA. This helps to stabilize the interaction between RARs and the DNA motifs to which they bind, RAREs, in complex with RXRs. This RAR/RXR association with the RARE is also dependent on the conformation of the specific RARE. Residues in C2 are critical for heterodimer formation.

RA-Binding Domain

The RA-binding domain (domain E) fulfills several important functions, including, of course, RA binding, along with transcription activation, and nuclear localization. The RA-binding domain binds both *all-trans* and *9-cis* stereoisomers of RA with high affinity. By contrast, the ligand-binding domain of RXRs binds only the *9-cis* RA isomer. These ligand-binding domains possess a series of 12 α -helical structures (H1–H12) that fold together to form the ligand-binding pocket. H12 contains the transcription activation domain AF-2. From X-ray crystallographic studies, it has been proposed that conformational changes which

Figure 1 Domain structure of RARs. All RARs and RXRs have domain structures similar to other members of the nuclear receptor family. Domains A–F are shown. DNA-binding domain (C) and ligand-binding domain (E) are highly conserved. Transcription activation functions are found in E (AF-2) and A (AF-1) domains.

occur as a result of the binding of RA alter the position of H12, and thus the ability of the AF-2 to interact with transcription factors that repress or activate gene transcription. In the mouse-trap model of ligand activation, H12 is extended into the solvent in the absence of RA but snaps shut once ligand enters the RA-binding pocket. These dynamic conformational reconfigurations result in differential interactions with cofactors that functionally link the receptor complex with the transcription initiation complex.

Other Functional Regions of RARs

The N-terminus of the RARs, comprising the variable domains A and B, contains another region important for transcriptional activation (AF-1). Interestingly, differential splicing/alternate promoter usage can give rise to multiple A domains for each subtype. This multiplicity of RAR isoforms and their potential to form partnerships with RXR subtypes create, at least conceptually, a remarkable number of combinatorial possibilities that may each have subtly different yet important contributions to RA target gene regulation. The B region also contains proline-rich motifs and phosphorylation sites for interactions with other proteins. Domain D, or the hinge region, has been described as a tether that connects DNA and ligand-binding functions. This domain also appears to possess a nuclear localization motif required to sequester receptors in the nucleus. Unlike steroid hormone receptors, which reside in the cell cytoplasm bound to heat-shock proteins that are released to the nucleus upon ligand binding, RARs and RXRs are complexed with DNA in their unliganded state. The role of the F-domain located at the extreme C-terminus of RAR is not known, but it contains phosphorylation sites that might have functional significance.

RA Response Elements

RAREs are DNA motifs to which RAR/RXR heterodimers can bind with high affinity. In most cases, these motifs comprise a direct repeat of the half-site consensus, PuGGTCA, separated by five base pairs; however, other configurations are also possible. These elements can be found in variations of number and orientation from within a few base pairs of transcription initiation sites to several thousand base pairs (usually upstream). These elements concentrate RAR/RXR heterodimers, which are normally in very low abundance, near transcription complexes.

RA Transcriptional Activation

RARs act as biosensors to detect RA in the local environment. The binding affinity of these receptors for RA is on the order of

10–30 nM. Once RAR-expressing cells are exposed to RA, changes in the pattern of gene transcription will occur. The role of transcription activators is to increase the efficiency of RNA polymerase II binding to the promoter and engage the successful transcription of a gene – and in the case of RARs, to do so only in the presence of RA. In unliganded form, the RAR/RXR heterodimer, when bound to an RARE on a target gene, can act to repress transcription (Figure 2). This complex recruits a specific type of transcription factor called a corepressor. Nuclear receptor corepressors found to interact with unliganded RAR include N-CoR/SMRT. The presence of RA causes allosteric modulation of the ligand-binding domain, shifting the cofactor binding preference from corepressor to coactivator. Thus, release of N-CoR/SMRT by RA results in the complex having increased affinity for coactivators such as the p140 and p160 subfamilies (e.g., steroid receptor coactivator (SRC)). Many coregulators that interact with RAR/RXRs and that also have other chromatin-remodeling functions, such as histone-deacetylase activity, kinase activity, or methylase activity, have been isolated. In addition to chromatin-remodeling functions, some of these cofactors correspond to factors critical for establishing a stable transcription initiation complex. The net effect of these interactions is increased or decreased transcription of target genes, depending on the promoter sequence, the local concentrations of factors binding to the promoter, and whether other signaling pathways are regulating the activities of any of these factors. In this way, the RA signal is processed in a manner that integrates the activities of many pathways of a given cell type.

RAR Function

Each of the murine RAR and RXR subtypes has been knocked out by homologous recombination in order to determine their functions during embryonic development and in the adult. Although there are multiple receptor isoforms, there are distinct roles for each defined by spatiotemporal distribution and promoter-specific activities. Throughout the murine life cycle, RAR α is ubiquitously expressed and may play a role in some general housekeeping functions. By contrast, RAR β transcript distribution indicates that this receptor may be involved in ontogenesis of the central nervous system during development and differentiation of epithelia in the adult. Similarly, the expression patterns of RAR γ are spatiotemporally regulated, suggesting that this receptor is involved in embryonic tail bud development, craniofacial morphogenesis, chondrogenesis, and maintenance of squamous epithelia. Among RXRs, RXR α is ubiquitously expressed, whereas RXR β and RXR γ are more restricted during embryogenesis.

Gene knockout studies confirmed distinct roles for each RAR and RXR subtype and also revealed a high level of functional redundancy. Whereas the RAR α - and RAR β -null mutants display some of the postnatal defects observed in vitamin A-deficient (VAD) mice (poor viability, growth deficiency, and male sterility), most of the RAR- or RXR-null single mutants exhibit only subtle or, in some cases, undetectable developmental abnormalities. By contrast, RAR double mutants exhibit reduced viability and recapitulate most symptoms of VAD.

Figure 2 The RAR/RXR complex regulates transcription. (a) Transcriptional repression occurs when unliganded RAR/RXR heterodimer binds to an RARE in the promoter region upstream of the transcription start site of an RA-responsive gene. Unliganded receptors bind to corepressor factors such as N-CoR/SMRT that act to limit the function of the transcription initiation complex (TIC) through reorganization of chromatin structure. (b) Binding of RA ligand to the RXR/RAR complex induces a conformational change in the ligand-binding domain of RAR, causing the release of N-CoR/SMRT and allowing the recruitment of transcriptional coactivators such as the p160 complex. This coactivator complex promotes the binding of transcription accessory factors essential for the efficient engagement of RNA pol II activity.

$\text{RXR}\beta^{-/-}\text{RXR}\gamma^{-/-}\text{RXR}\alpha^{+/-}$ triple-mutant mice exhibit marked growth deficiency but, surprisingly, display no obvious congenital or postnatal abnormalities. However, mutation of both $\text{RXR}\alpha$ alleles is lethal. Therefore, it is likely that $\text{RXR}\alpha$ carries out most of the vital developmental and postnatal functions of the RXRs, or is at least sufficient to do so.

Glossary

Cell transformation A complex alteration of cellular behavior that is characteristic of cancer cells. It involves a reduction in the dependence on soluble mitogens and anchorage to the extracellular matrix in order for the cells to proliferate, together with loss of the ability to respond to growth-inhibitory signals both from the extracellular environment or arising from intracellular checkpoint controls.

Cytoskeleton Filaments consisting of protein polymers that are responsible for giving the cell its mechanical strength, controlling its shape, and driving cell movement. Three types of filaments are found in animal cells: actin filaments, microtubules, and intermediate filaments.

Leading edge The front of an actively migrating cell, which generally displays a fan-shaped meshwork of actin filaments that push forward the plasma membrane as they polymerize and grow.

Small guanosine triphosphatases (GTPases) Monomeric guanosine triphosphate (GTP)-binding proteins, as opposed to the transmembrane receptor-coupled family of heterotrimeric G proteins, which bind guanine nucleotides and have different conformations when bound to GTP or guanosine diphosphate (GDP). This enables them to act as molecular switches and transiently activate several effector proteins.

The dynamic regulation of the actin cytoskeleton plays a crucial role in the control of cell shape and movement, and, therefore, is essential for the development and function of multicellular organisms. Accordingly, actin cytoskeleton regulators modulate a broad array of cellular processes such as cell migration, tissue morphogenesis, inflammation, vesicular trafficking, secretion, and cancer cell invasion and metastasis. Members of the Rho family of small guanosine triphosphatases (GTPases) are major regulators of the actin cytoskeleton in all eukaryotic cells. Similar to other small GTPases, these proteins are molecular switches that are exquisitely regulated by several positive and negative regulators that can switch them either on or off. Once activated, they bind to and activate a number of downstream effectors, most of them directly implicated in the regulation of actin-related biochemical events (e.g., actin polymerization). This enables Rho GTPases to act as key players in processes that require the dynamic regulation of the actin cytoskeleton.

Rho GTPase Family: Overview and Regulation

Rho GTPases are found in all eukaryotic organisms and constitute a separate highly conserved family within the larger Ras superfamily of small GTPases. In mammals, there are 20 Rho GTPases divided into eight subfamilies (Figure 1). The prototypical Rho family members are RhoA, Rac1, and Cdc42, which have been the most extensively characterized. Some Rho family members show a tissue-specific pattern of expression, although most of them are expressed in the majority of mammalian cells. They usually localize to cellular membranes as a consequence of lipid modifications at their carboxy termini, such as prenylation. Similar to other GTPases, Rho proteins bind to guanine nucleotides and most cycle between an

active guanosine triphosphate (GTP)-bound state and an inactive guanosine diphosphate (GDP)-bound state. Exceptions to this are the members of the Rnd subfamily (Rnd1, Rnd2, and Rnd3/RhoE), RhoBTB subfamily (RhoBTB1 and RhoBTB2), and RhoH (also known as TTF), which are constitutively GTP-bound. Three major types of regulators modulate the activation levels of Rho GTPases: guanine-nucleotide-exchange factors (GEFs), GTPase-activating proteins (GAPs), and guanine-nucleotide-dissociation inhibitors (GDIs), as illustrated in Figure 2. In addition, some Rho GTPases are regulated by expression levels, phosphorylation, which usually affects their subcellular localization, or by ubiquitination and subsequent degradation.

Guanine-Nucleotide-Exchange Factors

GEFs promote the release and exchange of bound nucleotides on the GTPase, effectively leading to an increase in the number of GTP-bound molecules due to the higher intracellular concentration of GTP. GEFs are, therefore, positive regulators of Rho GTPases that promote their activation. In mammalian cells, 80 GEFs have been described, which are divided into two groups. The first group, the Dbl-related GEFs, share a highly conserved exchange factor domain termed Dbl-homology (DH), named after the first GEF identified, Dbl. They have an adjacent pleckstrin homology (PH) domain, which helps to position the DH domain on membranes in the vicinity of the GTPases. In some GEFs, the PH domain also contributes to Rho GTPase binding. Most Dbl-related GEFs have other protein-protein interaction domains such as SH2 and SH3 domains, allowing them to be part of multi-protein complexes. The second group of GEFs are the DOCK

family proteins, which contain a Dock homology region 2 (DHR2) exchange factor domain. They also have a DHR1 domain that can mediate membrane interaction, similar to the PH domains of Dbf-related GEFs. GEFs can be regulated by binding to other proteins or by phosphorylation. Rho GEFs exhibit different degrees of specificity *in vitro* toward Rho

Figure 1 Phylogenetic tree of the Rho GTPase family. Rho GTPase family members can be grouped into eight subfamilies (shown in different colors) according to their sequence similarity.

GTPases, but it still has not been clearly established which GEFs regulate each of the Rho GTPase members *in vivo*.

GTPase-Activating Proteins

GAPs act by binding to the GTPase and enhancing hydrolysis of GTP, an otherwise slow and inefficient process, and by promoting the conversion of GTP to GDP they are negative regulators of Rho GTPases. Rho GAPs share in common a 140-amino-acid domain, termed the RhoGAP domain, which confers GAP activity. There are over 70 RhoGAPs in mammals. They are usually large proteins containing other domains involved in signaling and lipid and protein binding. These domains are thought to influence GAP function and localization in cells. Several RhoGAPs are known to be regulated by phosphorylation or lipid binding.

Guanine-Nucleotide-Dissociation Inhibitors

GDIs bind to some Rho GTPases and mask the prenyl groups at their C-termini, thus preventing their interaction with membranes, and with GEFs, GAPs, and downstream targets. For these reasons, they are considered to be negative regulators of Rho GTPases that sequester them in an inactive form in the cytoplasm. Signals that activate Rho GTPases will disrupt the GTPase/GDI complex and localize the GTPase to membranes. GDIs can be phosphorylated by a number of protein kinases, leading to their dissociation from GTPases and, consequently, to GTPase activation. There are three RhoGDIs in mammalian cells (α , β , and γ) that show differences in their pattern of expression, activity, and GTPase-binding specificity.

Figure 2 Rho GTPase regulation. Most Rho GTPases associate with membranes, and cycle between a GDP-bound inactive state and a GTP-bound active state. Some Rho GTPases can bind to RhoGDIs, which sequester them in the cytoplasm. Extracellular signals induce dissociation from RhoGDIs and the exchange of GDP for GTP, which is regulated by GEFs, thereby activating Rho GTPases and localizing them on membranes. In their GTP-bound form, Rho GTPases interact with their downstream effectors and regulate a variety of cellular responses, including changes to the actin cytoskeleton. Inactivation is achieved through GTP hydrolysis, which is promoted by GAPs binding to Rho GTPases.

Rho GTPase Family Activity: Downstream Targets

Rho GTPases exert their function by binding to and modulating the activity of an array of downstream effectors. Here, the manner in which Rho GTPases activate some of their most relevant targets in terms of actin cytoskeleton control will be described (Table 1).

Rho Effectors

The archetypical responses elicited by Rho (RhoA, RhoB, and RhoC) activation in cultured cells are the assembly of bundles of filamentous actin and myosin, termed stress fibers, and the formation of multimolecular complexes at the end of those fibers at sites of integrin-mediated cell adhesion, termed focal adhesions. Both effects can be largely attributed to one Rho effector, the serine/threonine kinase, Rho-kinase (ROCK). Rho-GTP binding to ROCK unfolds and relieves its kinase domain from an otherwise closed, autoinhibited, conformation. The two isoforms of ROCK phosphorylate a number of proteins involved in regulating the actin cytoskeleton, including the myosin-binding subunit of myosin light-chain phosphatase, thereby inhibiting its phosphatase activity and enhancing myosin light-chain phosphorylation and actomyosin-based contractility. Other Rho effectors contribute to Rho-mediated actin cytoskeleton regulation, such as mDia proteins (mammalian Diaphanous-related formins). mDia proteins bind as dimers to barbed (or plus) ends of

actin filaments and act as actin nucleators promoting the growth of parallel, unbranched, filaments.

Cdc42 Effectors

Activation of Cdc42 in most cells promotes the formation of filopodia, spike-like membrane protrusions induced by actin polymerization in parallel bundles. As with Rac-induced lamellipodia, these structures are associated with the leading edge of migrating cells. Cdc42 induces the formation of filopodia through the activation of several targets, including formins mDia formins, which are actin nucleators, and IRSp53, an adaptor protein with an inverse-Bin-amphipysin-Rvs (BAR) domain that bends membranes. Cdc42 also acts through its target N-Wiskott-Aldrich syndrome protein (N-WASP) and the hematopoietic-specific WASP to regulate vesicle trafficking and the formation of podosomes and invadopodia, actin-based structures at the plasma membrane that mediate localized degradation of extracellular matrix proteins. WASP proteins induce *de novo* actin polymerization through their binding to the Arp2/3 (actin-related protein) complex, which acts as an actin nucleator. Binding of active Cdc42 to WASP changes its conformation, relieving it from an autoinhibited state and exposing a previously masked domain, the VCA domain (verprolin-homology, cofilin-homology, and acidic region). Once exposed, this domain binds to G-actin through the V-domain and to the Arp2/3 complex through the CA-domain, strongly activating Arp2/3 complex-induced actin nucleation and polymerization. WASP also binds to the actin-binding protein profilin, which further enhances WASP-mediated actin filament formation through its adenosine triphosphate/adenosine diphosphate (ATP/ADP) exchange activity toward actin. Activation of WASP family proteins by Rho GTPases, such as WASP activation by Cdc42, is a typical example of downstream effector activation by binding to active GTPases (Figure 3).

Rac Effectors

In most mammalian cells, activation of Rac induces lamellipodia and membrane ruffles, both being broad sheet-like plasma membrane protrusions that extend over the substratum or upward, respectively. These protrusions are driven by a branching network of actively polymerizing actin filaments, and are usually found at the leading edge of migrating cells. The Rac effector pathway that leads most directly to actin polymerization involves WAVE proteins (wasp/verprolin homologous protein). WAVEs are members of the WASP family, and are part of a multiprotein complex mediating actin polymerization through activation of the Arp2/3 complex. Rac does not bind directly WAVEs but to CYFP4/Sra-1, which is part of the WAVE complex. Although the mechanism whereby Rac1 regulates the WAVE complex is different to Cdc42 stimulation of WASP, the consequence in both cases is to stimulate actin polymerization (see Figure 3). Other Rac effectors also contribute to actin polymerization and to extension of lamellipodia and membrane ruffles. For example, p21-activated kinases (PAKs) are a family of kinases that can be activated by Rac and Cdc42 and contribute to actin reorganization, for instance, through phosphorylation of LIM kinase, which phosphorylates and inhibits the actin-filament severing and depolymerizing protein cofilin, thereby increasing the level of polymerized actin.

Table 1 Rho GTPase, downstream effectors and their functions

<i>Rho GTPase</i>	<i>Downstream effectors</i>	<i>Function in cell biology</i>
RhoA, B, C	ROCK1,2	Actomyosin contractility: stress fiber and focal adhesion formation, tail retraction in migrating cells
	mDia	Actin nucleator promoting actin filament formation
Rac1, 2, 3	CYFP1/Sra-1	Part of WAVE complex, which stimulates actin polymerization through the Arp2/3 complex, inducing lamellipodium formation
	PAK1, 2, 3	Actin filament stability through LIMK-induced cofilin inhibition; focal adhesion turnover
Cdc42	WASP/N-WASP	Actin polymerization through Arp2/3 complex. Vesicle trafficking; invadopodia and podosomes
	IRSp53	Adaptor protein involved in filopodium formation
	mDia	Actin nucleator involved in filopodium formation
	Par6	Part of PAR complex involved in cell polarity
Rnd1, Rnd3	p190RhoGAP	Antagonize RhoA effects: disassembly of actin stress fibers and focal adhesions.
RhoG	ELMO/DOCK180	Lamellipodium extension, cell migration
RhoH	Unknown	Inhibits Rac1 signaling and migration in hematopoietic cells
RhoQ	Unknown	Involved in vesicle trafficking

Figure 3 Model of effector activation by Rho GTPases: Cdc42-induced WASP activation promotes actin polymerization. When Cdc42 is inactive, WASP is in an auto-inhibited conformation. Upon Cdc42 activation, inactive WASP binds to Cdc42–GTP through its CRIB domain, relieving its inhibitory conformation and exposing its VCA domain. The VCA domain is now available to recruit and activate the Arp2/3 complex, stimulating actin polymerization.

Other Rho Family Members

Although RhoA, Rac1, and Cdc42 are the most extensively studied members of the Rho family, other Rho GTPases also regulate the actin cytoskeleton (Table 1). First of all, closely related isoforms of these proteins such as RhoB or Rac2 appear to have distinct roles in regulating the actin cytoskeleton and cell adhesion. The Rnd proteins are unusual examples of GTP-binding proteins, as they do not cycle between an active GTP-bound state and an inactive GDP-bound state. Rnd1 and Rnd3 have been shown to antagonize RhoA in its effects on the actin cytoskeleton, promoting stress fiber and focal adhesion disassembly in several different types of mammalian cells. RhoH seems to antagonize some of the Rac1 GTPase functions related to lamellipodium extension and hence cell migration. Other members have more similar effects to those of the prototypical Rho GTPases: RhoG signals in parallel to Rac to regulate lamellipodium extension and cell migration, whereas RhoJ/TC10 is more related to Cdc42 and regulates vesicle trafficking.

Rho GTPase Family: Functions in Cell Biology

The ability to regulate the actin cytoskeleton dynamically enables Rho GTPases to be involved in many cellular processes, the most obvious of them being cell migration. However, there are many other processes that require Rho GTPases, such as secretion, endocytosis, and cell proliferation.

Cell Migration

Cell movement requires an orchestrated spatio-temporal regulation of the actin cytoskeleton, which involves coordinated activation of several members of the Rho GTPase family. Rac isoforms are important to induce actin polymerization in the

leading edge of the cell, in the form of lamellipodia and membrane ruffles, pushing forward the plasma membrane and generating the driving force for cell motility. Rac activity is also crucial to form adhesions as cells move forward and interact with new extracellular matrix. Rho contributes to cell motility by providing actomyosin-based contractility necessary for cell body contraction and tail retraction, and also has a role at the leading edge in lamellipodium extension. Cdc42 induces actin polymerization in invadopodia, which are involved in degrading the extracellular matrix to allow cells to migrate through a three-dimensional environment. In addition, Rho GTPases affect microtubule dynamics, which is also important for cell migration. For example, Cdc42 is important for directional migration and chemotaxis in some cell types, predominantly by acting through the Par complex and polarizing the microtubule cytoskeleton. Although the principal roles of Rho GTPases in cell migration have been already established, there are important differences in the role that these proteins have in different cell types, such as epithelial cells versus macrophages. Furthermore, it is not yet fully understood how these proteins and their effectors are spatially and temporally regulated, and how such an exquisite level of coordination in their functions is achieved in cell migration.

Secretion and Endocytosis

Vesicle trafficking requires both the actin cytoskeleton and the microtubule network, and several Rho GTPases have been shown to affect different aspects of vesicle trafficking. For example, Cdc42 is involved in endocytosis and Golgi-to-endoplasmic reticulum (ER) transport, and this involves its downstream target N-WASP. In addition, three less-studied Rho family members, RhoB, RhoD, and RhoQ, have been found to localize to endosomes and modulate endosome dynamics.

Proliferation and Transformation

Both Rho and Rac isoforms have been shown to affect cell proliferation. Although Rho effectors are important for the actin ring contraction that drives cytokinesis, it is in the G₁ phase of the cell cycle where Rho GTPase function seems to be contribute to cell-cycle progression. Activation of both Rho and Rac has been linked to the activation of cyclin-dependent kinases by regulating the expression of D-type cyclins and cyclin-dependent kinase inhibitors, such as p21^{cip1} and p27^{kip1}. In contrast to conventional Rho GTPases, Rnd3 negatively regulates cell proliferation by inhibiting cyclin D1 expression. However, the downstream effectors that lie between Rho GTPases and cell-cycle regulators remain unknown. Interestingly, Rho GTPases also contribute to cell transformation. The expression and activity of several Rho GTPases are increased in cancer, correlating with tumor progression. Active mutants of Rho, Rac, and Cdc42 all have positive effects on cell transformation and anchorage-independent growth, although they are not known to be mutated in human tumors. However, their biological effects on cell proliferation and actin cytoskeleton place them as potentially important mediators of neoplastic transformation. For instance, their crucial role in cell motility has been shown

to influence the loss of epithelial polarity and invasiveness of cancer cells.

Ribosomal proteins Proteins that are present in mature, functioning ribosomes.

RNA helicases RNA-dependent ATPases that catalyze pairing or unpairing of RNA or alteration of RNA–protein interactions.

RNA processing Removal of internal or 5′ or 3′ flanking sequences by exo- and endonucleolytic processing.

RNA–protein interactions Noncovalent interactions between RNA and proteins.

Structural proofreading The process of surveilling misassembly of ribosomes.

Introduction

Ribosomes are ribonucleoprotein (RNP) nanomachines that synthesize proteins. The small subunit (SSU) brings messenger RNA (mRNA) and transfer RNA (tRNA) together in the decoding center, and the large subunit (LSU) catalyzes peptide bond formation in the peptidyl transferase center. Exquisite high-resolution structures of these ancient multimolecular machines have facilitated informed predictions about ribosome function. While their function is phylogenetically conserved, there are differences in the size and complexity of ribosomes in prokaryotes and eukaryotes. In prokaryotes and archaea, the 30S ribosomal subunit contains the 16S ribosomal RNA (rRNA) and 20 ribosomal proteins (r-proteins), while the 50S ribosomal subunit is composed of 23S and 5S rRNAs, and 34 r-proteins. Eukaryote ribosomes are more complex. The 40S subunit of eukaryotes is composed of 18S rRNA and 33 r-proteins, and the 60S subunit consists of 25S, 5.8S, and 5S rRNAs, and 47 different r-proteins. The presence of insertion elements in eukaryotic rRNAs (referred to as expansion segments), and 20–30 additional r-proteins, might account for observed mechanistic differences between prokaryotes and eukaryotes during the initiation and elongation phases of translation, thereby providing more flexibility for regulation of translation in eukaryotes.

In this article, we focus on what has been learned about how multiple, dynamic protein–protein, RNA–RNA, and RNA–protein interactions are established and rearranged during the assembly of ribosomes both *in vitro* and *in vivo*. Ribosome assembly requires coordination of several processes: synthesis, folding, modification, and nucleolytic processing of pre-rRNAs, and ordered binding of r-proteins to the pre-rRNA. In prokaryotes, ribosome assembly and function occur in the same compartment, whereas these processes are largely but not completely segregated in eukaryotes. Ribosome biogenesis begins with transcription of rDNA genes in the nucleolus, and subsequent maturation occurs upon release of assembling ribosomes into the nucleoplasm to enable export, and even in the cytoplasm, prior to establishing functional subunits.

Model Systems

Much has been learned about ribosome biogenesis from studies of bacterial ribosome assembly *in vitro* and from analysis of yeast ribosome synthesis *in vivo*. More recently, investigations of metazoans are revealing how dysregulation of ribosome biogenesis results in various diseases. Analysis of the nucleotide sequence of genomes from prokaryotic and eukaryotic model organisms demonstrates that many r-proteins are conserved. Whereas the primary sequence of rRNAs is not completely conserved between prokaryotes and eukaryotes, the secondary structure of rRNAs is conserved. Thus, the principles and mechanisms of ribosome assembly learned from bacteria and yeast will be applicable to other organisms.

Assembly Principles Learned from *In Vitro* Studies

Functional bacterial 30S and 50S ribosomal subunits can be reconstituted *in vitro* from rRNA plus each of the ribosomal proteins. Detailed studies of the biochemical and biophysical principles underlying ribosome assembly *in vitro* have provided useful paradigms to guide investigations of ribosome biogenesis *in vivo*.

One of the first principles revealed by these experiments is that assembly of r-proteins into ribosomal subunits occurs in a hierarchical manner. Reconstitution studies of bacterial 30S ribosomal subunits defined an ‘assembly map’ for the order of association of each r-protein with rRNA. Based on their order in the binding hierarchy, r-proteins are designated as primary (binding directly to rRNA), secondary (binding is dependent on primary binding proteins), or tertiary proteins (binding is dependent on secondary binding proteins). While such a dependency map has proved to be a very useful starting point, it does not provide any information on the kinetics of protein binding. Rather, the pathway of assembly may largely reflect the order in which each r-protein is most stably associated with rRNA. Additionally, the assembly map does not take into account either the folding pathway of 16S rRNA

independent of r-proteins or the role in ribosome assembly of nucleolytic processing of rRNA precursors that occurs *in vivo*. More recently, these aspects of 30S subunit assembly have been explored in greater detail using techniques such as chemical and hydroxyl radical probing of RNA conformation to assay changes in rRNP conformation with time, and pulse-chase/mass spectrometry (PC/MS) to determine kinetics of r-protein binding to rRNA.

A possible explanation for the observation of primary binding r-proteins in the assembly map is that their binding sites are created at least in part by the conformation adopted by 16S rRNA independent of r-proteins. In fact, consistent with this idea and the view that ribosomes have evolved from an RNA catalyst, it has been shown that the 5' domain of 16S rRNA can fold and form tertiary contacts in the absence of all r-proteins. This tertiary structure is presumably not completely stable in the absence of protein contacts and, thus, is most likely stabilized by the binding of r-proteins to sites that are created by transient conformations adopted by rRNA as it undergoes folding. Therefore, the second principle suggests that rRNA folding provides the basis of r-protein binding during ribosome assembly.

A third principle that has emerged from *in vitro* studies of bacterial ribosomes is that strengthening of r-protein binding with rRNA occurs as ribosome assembly progresses. Many r-proteins contact multiple nucleotides on rRNA. Time-resolved hydroxyl radical footprinting has revealed that some of these nucleotides are protected before others, suggesting that as ribosome biogenesis advances, r-proteins make more contacts with rRNA, thereby becoming more stably integrated with ribosomes.

The initial establishment of a few contacts between r-proteins and rRNA potentially stabilizes certain RNA conformations, and induces changes in rRNA conformation to provide binding sites for additional (secondary or tertiary) r-proteins. Therefore, r-protein binding consolidates RNA folding gains and imparts directionality to the assembly process. This suggests a model where assembly proceeds through an alternating series of RNA conformational changes and protein binding, which sequentially stabilize the final RNA structure. Kinetic data have revealed that assembly of mature 30S subunits occurs via multiple, parallel RNA folding pathways, all of which converge on the final product. This has led to the concept of an assembly landscape as opposed to a unique pathway over which assembly of ribosomal subunits occurs.

Finally, *in vitro* studies have revealed that ribosome assembly occurs in the 5' to 3' direction. PC/MS and chemical probing of secondary structure of rRNA have shown that r-protein binding to the 5' domain of rRNA can be observed before protein contacts are established with the 3' domain of rRNA. By contrast, hydroxyl radical footprinting assays showed an initial burst of nucleotide protection all along 16S rRNA indicating that RNA folding nucleates from many different sites spread across the RNA, and thus pointing to a lack of 5' to 3' directionality in assembly. These conflicting observations can be reconciled by taking into account the nature of the different experimental setups. PC/MS measures the kinetics of protein binding to rRNA, and as such only stable r-protein–rRNA interactions can be detected because r-proteins that bind weakly during the pulse can be washed off during the chase. Footprinting assays, on the other hand, can capture nucleotide protection by both weakly-interacting and stably-associated

r-proteins. Taken together, these data indicate that while ribosome assembly can nucleate across the entire rRNA, the final tight association of r-proteins with rRNA occurs in a 5' to 3' direction.

It is important to consider how these *in vitro* experiments might or might not reflect assembly *in vivo*. For example, when ribosome assembly occurs *in vivo*, it is coupled with transcription of rRNA, which also presumably contributes to the observed 5' to 3' directionality of r-protein association. rRNA may have evolved to fold 5' to 3' as it is synthesized, and to incorporate r-proteins thusly, thereby coupling assembly with transcription of rRNA. Furthermore, the requirement of a heating step during reconstitution of ribosomal subunits *in vitro* and the identification of a number of bacterial mutants that are defective in production of ribosomes indicate the need for *trans*-acting factors during ribosome biogenesis *in vivo*.

Eukaryotic Ribosome Biogenesis *In Vivo*

Synthesis and Processing of rRNA

In yeast, the 9.1-kb rDNA fragment encoding all four rRNAs is present as 100–200 tandem repeats on chromosome XII. The high copy number of these genes enables cells to produce large quantities of ribosomes when necessary, for example, ~40 ribosomes per second in rapidly dividing yeast cells. Transcription of the 35S precursor containing three of the four rRNAs is carried out by RNA polymerase I in the nucleolus, while pre-5S rRNA is independently transcribed by RNA polymerase III. The 35S pre-rRNA contains sequences encoding the 25S, 18S, and 5.8S rRNAs flanked by 5' and 3' external transcribed spacers (ETSs) and separated by internal transcribed spacers 1 and 2 (ITS1 and ITS2). The predicted secondary structures of the mature rRNAs are highly conserved. Although these features are somewhat less conserved for spacer sequences, it appears that their secondary structures are important for their removal. The gene encoding 5S rRNA is separated from the gene encoding 35S pre-rRNA by intergenic sequences (IGSs), which are transcribed by RNA polymerase II to synthesize, at low levels, noncoding RNAs. Transcription by RNA polymerase I leads to silencing of these noncoding RNAs, perhaps through a mechanism involving modification of histone acetylation. Concurrent with or immediately following transcription, the 35S pre-rRNA is covalently modified by the box C+D and box H+ACA snoRNPs. They are composed of snoRNAs, which guide the snoRNPs to sites of modification on rRNA by base pairing with the rRNA. Methylases and pseudouridylylases present in the box C+D and box H+ACA snoRNPs, respectively, then carry out modification of the appropriate nucleotides. These sites of modification are located within conserved, functionally important domains of mature rRNA.

The presence of three of the four mature rRNAs within one transcript, one of which ends up in the 40S subunit and the other two in the 60S subunit, presumably ensures that stoichiometric amounts of rRNAs are delivered to 40S and 60S subunits. Furthermore, proper timing of removal of the spacer sequences could potentially allow pre-rRNA processing to be subject to cues from the cellular environment to regulate ribosome biogenesis. A more interesting potential role for these spacers is to ensure proper folding of rRNA by enabling,

for example, base pairing between different mature rRNA sequences required for formation of functional ribosomes.

Three successive cleavages by unidentified nucleases at sites A_0 , A_1 , and A_2 generate the 20S pre-rRNA and 27SA₂ pre-rRNAs, thus separating the mature rRNAs of the 40S and 60S ribosomal subunits (Figure 1). The 20S pre-rRNA is exported to the cytoplasm where its 3' end is cleaved to form the 18S rRNA. This is the last known step in the formation of 40S ribosomal subunits. Processing of 27SA₂ pre-rRNA to form mature rRNAs of the 60S ribosomal subunit is more complex. Alternative pathways generate two forms of the 27SB pre-rRNA – the major, short form 27SB_S pre-rRNA (~85%) and the 27SB_L pre-rRNA (~15%), which is ~7 nt longer at its 5' end. In the major pathway, the 27SA₂ pre-rRNA is cleaved at the A_3 site by RNase MRP, followed by exonuclease digestion from the A_3 site to the B_{1S} site by the exonucleases Rat1, Xrn1, and Rrp17. In the alternative pathway, 27SA₂ pre-rRNA is endonucleolytically processed at the B_{1L} site to create the 27SB_L pre-rRNA. The processing of 27SB_S and 27SB_L pre-rRNAs to 25S rRNA and 5.8S_S or 5.8S_L rRNAs, respectively, is thought to be identical. Cleavage at site C_2 by an unknown endonuclease separates the precursors of the 5.8S and 25S rRNAs, the 7S pre-rRNA and the 25.5S pre-rRNA respectively. Subsequent 3' processing of 7S pre-rRNA by the exosome complex and 5' processing of 25.5S pre-rRNA by the exonucleases Rat1 and Xrn1 eventually lead to the formation of mature 5.8S and 25S rRNAs. While the identity of some exo- and endo-nucleases involved in pre-rRNA processing is known, many of these nucleases remain to be discovered.

Pre-Ribosomal Intermediates and the Roles of Assembly Factors

Initial studies revealed a crude outline of the assembly pathway (Figure 2). 35S pre-rRNA is present in 90S pre-ribosomes (pre-rRNP) that give rise to 43S and 66S pre-rRNP assembly intermediates. These precursor particles are then converted to the mature 40S and 60S ribosomal subunits, respectively. The 43S assembly intermediate contains the 20S pre-rRNA. There are at least six 66S assembly intermediates containing the 27SA₂, 27SA₃, 27SB_L or 27SB_S, 25.5S + 7S, and 25S + 5.8S rRNAs, respectively.

Each of these pre-rRNPs contains a subset of the r-proteins found in mature subunits, plus a number of nonribosomal proteins/assembly factors not present in mature functioning ribosomes. More than 200 such *trans*-acting factors required for assembly of ribosomes have been identified in yeast, using genetic screens or selections to identify mutants defective in ribosome biogenesis, or using proteomic approaches to purify and characterize assembly intermediates. Recently, metazoan counterparts of most of these proteins have been identified by mass spectrometry of proteins from purified nucleoli. These assembly factors include potential RNA-binding proteins, scaffolding proteins, RNA helicases/RNPases (DEXD/H box proteins), AAA+ ATPases, GTPases, kinases, and interestingly, ribosome-like proteins.

While initial characterization assigned most factors to one or more steps in pre-rRNA processing/subunit assembly, more

Figure 1 Pre-rRNA processing pathway in *Saccharomyces cerevisiae*. The initial 35S pre-rRNA transcript, synthesized by RNA polymerase I, contains sequences for mature 18S, 5.8S, and 25S rRNAs (cylinders) along with internal and external transcribed spacer sequences (thin horizontal lines). Sites on pre-rRNA at which processing occurs are indicated on the 35S pre-rRNA transcript. Processing intermediates that form during ribosome assembly are indicated. Exo- and endo-nucleases, where known, are mentioned alongside the step in which they function.

Figure 2 Pathway of assembly of 60S and 40S ribosomal subunits in *Saccharomyces cerevisiae*. The red circle represents 90S pre-ribosomes; subsequent 66S and 43S pre-ribosomes are shown as orange circles. The pre-rRNA processing intermediate present in each pre-ribosomal particle is indicated within the circles. Yellow circles represent mature 60S and 40S ribosomal subunits. Subcellular compartments within which different pre-ribosomal intermediates are formed are indicated.

specific roles of assembly factors have been experimentally verified in only a few cases. An interesting example is the kinase Hrr25, which is required for structural reorganization during the final stages of maturation of 40S ribosomal subunits. Phosphorylation and subsequent dephosphorylation of rpS3 by Hrr25 enable tighter binding of this r-protein to 40S precursors and reorganizes the beak structure, formed in part by 18S rRNA. Another example is the GTPase Bms1, which in its GTP-bound form has been shown to interact with Rcl1, a putative endonuclease, and U3 snoRNA, during an early step of 40S subunit assembly. GTP hydrolysis causes Bms1 to be released from pre-ribosomes leaving behind Rcl1 on pre-rRNPs. Thus, Bms1 is thought to function as a GTP-regulated switch that delivers Rcl1 to pre-ribosomes. By contrast, GTPases required for assembly of 60S ribosomal subunits are thought to function later in the assembly pathway and lead to dissociation and recycling of assembly factors. The same is true for AAA+ ATPases, the most well-studied of which is Rea1. Rea1 is thought to use the energy of adenosine triphosphate (ATP) hydrolysis within its ring domain to create a tensile force, which results in the release of several different assembly factors from two distinct regions of pre-ribosomes. Rea1-mediated dissociation of assembly factors occurs just prior to nuclear export of pre-ribosomes.

Compartmentalization of assembly: structural proofreading

Late steps in ribosome biogenesis in yeast occur in the cytoplasm, where a few remaining assembly factors are released to generate translation-competent ribosomal subunits. It is thought that structural proofreading monitors correct assembly of ribosomes, and ensures that incorrectly assembled pre-ribosomes are not exported to the cytoplasm. Such a quality-control

mechanism would couple export of ribosomal precursors with late maturation events. In principle, export factors could only bind to properly assembled ribosomal subunits. Furthermore, the presence of some assembly factors might prevent incompletely assembled ribosomes from functioning prematurely in translation. The export factor Nmd3 has been shown to interact genetically with the mRNA exporters Mex67/Mtr2, suggesting that Mex67/Mtr2 might also enable export of pre-60S ribosomal subunits through interactions with the nuclear pore complex (NPC). In addition to Mex67/Mtr2, the shuttling assembly factor Arx1 is also thought to facilitate export of pre-60S subunits, via interactions with the NPC. Both Nmd3 and Arx1 have been shown to accompany 60S ribosomal subunits to the cytoplasm (Figure 3).

The assembly factors Tif6, Mrt4, Alb1, and Rlp24/Nog1 also accompany pre-60S ribosomal subunits to the cytoplasm, where they are released in a step-wise manner by the activity of ATPases and GTPases, thereby generating functional 60S ribosomal subunits. The first step is initiated by the AAA+ ATPase Drg1, which releases the assembly factors Nog1 and Rlp24. The release of the ribosome-like protein Rlp24 enables association of the r-protein, rpL24. The Drg1-mediated release of assembly factors is followed by two events – the release of Arx1/Alb1 by Rei1/Jjj1/Ssa and the assembly of the P0 stalk. The dual-specificity phosphatase Yvh1 is required for the removal of another ribosome-like protein Mrt4, which in turn enables stable association of the ribosomal protein P0. Assembly of the P0 stalk is thought to recruit the GTPase Efl1 for release of Tif6. The release of Nmd3 by the GTPase Lsg1 and the r-protein rpL10 is thought to be the last event in the cytoplasmic maturation of 60S ribosomal subunits. With the release of Nmd3, the mature 60S ribosomal subunit is formed, ready to engage in translation.

Figure 3 Association of assembly factors with pre-ribosomal intermediates. Pathway of assembly of 60S ribosomal subunits is shown. Each horizontal line spans all pre-ribosomal intermediates with which a specific assembly factor associates. Assembly factors (except those in italics) are organized into different physical subcomplexes. The blue vertical arrow indicates the pre-rRNA processing step for which each physical subcomplex is required. Assembly factors in italics are those required for structural proofreading. They do not form a physical neighborhood. Refer to text for details of step-wise dissociation of these late factors.

Role of Ribosomal Proteins in Ribosome Biogenesis

In yeast, most r-proteins are essential for growth, indicating either a more expansive role for r-proteins in eukaryotic ribosomes or else that some might have extraribosomal roles. Because of a preoccupation with assembly factors, with a few notable exceptions, the role of r-proteins in pre-rRNA processing and ribosomal subunit maturation went largely unstudied for a long time. Pioneering work by Milkereit and colleagues corrected this imbalance by analyzing the role of SSU r-proteins in the formation of 40S subunits. They found that most essential SSU r-proteins were required for formation of 18S rRNA and many were required for efficient export of pre-40S particles to the cytoplasm. Stable association of r-proteins with 43S pre-ribosomes is important for significant restructuring events such as formation of the head-like and body-like regions of 40S ribosomal subunits. Furthermore, consistent with *in vitro* studies of bacterial ribosome assembly, it has been shown that r-protein binding with pre-ribosomes is strengthened as pre-rRNA processing and assembly proceed. A study with the LSU r-proteins in yeast has shown that the essential r-proteins of the 60S subunit can also be grouped based on the pre-rRNA processing step(s) for which they are required.

Studying Physical Neighborhoods to Understand Ribosome Assembly

One approach to simplify the study of ribosome biogenesis, while taking into account the cooperativity that exists during the assembly process, is to understand how small physical

subcomplexes or neighborhoods are constructed within nascent ribosomes. Physical clusters likely contain molecules, many or all of which are required for the same step in ribosome assembly (Figure 3). A number of such physical subcomplexes have been identified, each of which is required for a specific step of maturation of 66S pre-rRNPs. By studying when members of a physical neighborhood associate with (and dissociate from) pre-ribosomes, how they interact with each other, and their interdependencies for association with pre-ribosomes, one can model how assembly factors and r-proteins within a physical neighborhood cooperate with each other to enable a specific step in maturation of ribosomal subunits to occur efficiently.

One of the emerging principles underlying the formation of pre-ribosomal particles is the stepwise or ordered binding of such discrete subcomplexes to pre-rRNA. This principle is exemplified by studies on the formation of 90S pre-rRNPs, where assembly of the t-UTP subcomplex leads to the ordered binding of five additional subcomplexes through two mutually independent assembly routes. This has given rise to a view of the 90S pre-ribosome as a modular structure that is constructed in a hierarchical fashion. Similar principles can be expected to underlie the formation of 66S pre-rRNPs. Constructing such large RNPs from multiple smaller subcomplexes, therefore, provides a means to simplify the assembly process.

Quality Control of Ribosomal Subunits

Given that ribosome assembly requires the coordinated functions of many proteins and RNAs, and constant structural

changes, there is a high probability that a certain fraction of ribosomes will be misassembled. Such aberrant particles might be detrimental to cells by interfering with protein synthesis directly or indirectly. Therefore, it is important that such misassembled ribosomal subunits are recognized, thereby recruiting quality-control machinery to degrade nonfunctional ribosomes. Indeed, such quality-control pathways to turn over dysfunctional mature ribosomes exist. rRNA mutations in the decoding or peptidyl transferase center (PTC) of ribosomes are recognized and subjected to nonfunctional rRNA decay (NRD). However, it appears that there are mechanistically distinct NRD pathways involved in turnover of 40S and 60S ribosomal subunits. The NRD of nonfunctional 40S subunits is similar to no-go decay (NGD) of mRNA. By contrast to 40S subunits, it has been shown that nonfunctional 60S ribosomes are subject to active ubiquitin-dependent degradation. This underscores the fact that turnover of 60S and 40S subunits occur independently of each other.

In addition to surveillance of the functionality of mature ribosomal subunits that occurs in the cytoplasm, it appears that there might be nuclear quality control processes in place to monitor aberrant pre-ribosomal assembly intermediates. Interestingly, when ribosome biogenesis is blocked, rRNA precursors fail to accumulate to high levels. It has been shown that the Trf4/5, Air1, Mtr4 polyadenylation (TRAMP) complex is involved in the polyadenylation of rRNA precursors that could lead to exosome-mediated degradation of aberrant intermediates.

Ribosome Biogenesis and Disease

Mutations in both r-proteins and assembly factors have been shown to result in a variety of genetic disorders. This came as a surprise because it has long been thought that such mutations would be lethal because of the essential nature of the proteins and the process in which they function. Furthermore, all these diseases show some degree of tissue-specificity, which is intriguing given that ribosomes are present in all cell types in the body. Mutations in assembly factor genes can act as the causative agent, or, in some cases they can exacerbate the effect of a mutation in a non-pre-ribosome associated gene product. These mutations result in a variety of diseases ranging from alopecia and male infertility to Dyskeratosis congenita and Prader-Willi syndrome. Dyskeratosis congenita is caused by a mutation in the *DKC1* gene, which encodes dyskerin, a pseudouridine synthase required for rRNA modification and is characterized by premature ageing and increased susceptibility to cancer. Mutations in the r-protein S19 have been shown to result in another syndrome called Diamond-Blackfan anemia, which typically also results in increased cancer susceptibility. Understanding the molecular mechanisms underlying diseases caused by defects in ribosome biogenesis is an important challenge for the future.

The link between ribosome biogenesis and cancer is complicated, and therefore not very well understood. rRNA synthesis is tightly coupled with cell-cycle progression, to ensure proper cell growth and proliferation. The tumor suppressor p53 is known to repress RNA polymerase I, and in cancer cells carrying mutations in p53, RNA polymerase I activity is derepressed, leading to increased rRNA synthesis. Similarly, r-proteins are also upregulated in cancer cells, thus amplifying the number of functional ribosomes in the cell. This would have the effect of increasing the translation rate in cells and therefore promoting transformation. Because r-protein expression is upregulated in cancer cells, it is still unclear how loss of an r-protein could contribute to neoplasm. It is conceivable that haploinsufficiency of r-proteins would affect ribosome biogenesis, resulting in a decrease in global translation of mRNAs, including those encoding tumor suppressor genes. Thus loss of r-proteins could result in cancer. Recently, it has been shown that haploinsufficiency of *RPS6* and *RPS7* (leading to reduced levels of these proteins) affects 40S subunit biogenesis and leads to p53 activation and apoptosis through a mechanism based on translation of RPL11. Under conditions of reduced *RPS6* and *RPS7*, even though there is a reduction in global translation levels, there is increased translation of mRNAs with a polypyrimidine tract at the transcription start (5'-TOP mRNAs). Since all mRNAs encoding r-proteins contain a 5'-TOP, the resulting overexpression of RPL11 would inhibit MDM2/HDM2, thereby activating p53 and promoting cell death and apoptosis. It is still unclear how haploinsufficiency of r-proteins can lead to apoptosis on the one hand and promote tumorigenesis on the other. The mechanisms underlying these complex signaling pathways, their relationship with each other, and their response to different cellular stimuli need to be investigated in greater detail.

Glossary

Elongation factor G (EF-G) The protein factor responsible for catalyzing the translocation step of protein synthesis.

Elongation factor TU (EF-Tu) The protein factor responsible for delivery of aminoacyl-tRNA to the ribosome.

Hybrid tRNA-binding states The binding state of peptidyl-tRNA, in which the anticodon end is in the A site of the 30S subunit and the acceptor end is in the P site of the 50S subunit, and deacyl-tRNA is in the 30S P site and 50S E site. This designation is relative to the classical tRNA-binding states, as defined originally, with the A site as the binding site for aminoacyl-tRNA and the P site as the binding site for peptidyl-tRNA.

Ribosome The universal particle responsible for protein synthesis in all organisms. It is composed largely of ribosomal RNA (rRNA), the folding of which to adopt an active conformation is aided by ribosomal proteins.

Substrate proofreading The rejection of noncognate or near-cognate substrates prior to polymerization, in contrast to product proofreading used by DNA polymerases to remove erroneously incorporated monomers from nascent polymer chains.

Transfer RNA (tRNA) RNA molecules of around 76 nucleotides that are the substrates of the ribosome. They contain triplet base sequences called anticodons that base pair with the corresponding codon of messenger RNA (mRNA) in the 30S subunit during translation. Amino acids are attached to the 3' end of tRNAs.

Translocation The movement of tRNAs and mRNA by one codon through the ribosome during protein synthesis.

tRNA selection The process by which the ribosome, together with EF-Tu, discriminates between aminoacyl-tRNAs based on the codon present in the ribosomal A site. This is also often referred to as decoding.

Introduction

Protein synthesis is a highly complex, multistep process that universally occurs on the 2.5-million-Da ribonucleoprotein particle called the ribosome. Ribosomes consist of two subunits of unequal size and are composed primarily of RNA. The most thoroughly studied ribosomes are those of bacteria, whose small or 30S subunit consists of a single 16S ribosomal RNA (rRNA) molecule and around 20 ribosomal proteins, and whose large or 50S subunit consists of single 23S and 5S rRNA molecules and around 30 ribosomal proteins. Ribosomes from eukaryotes are composed of slightly larger rRNA molecules with additional ribosomal proteins. These large RNA molecules fold into complex three-dimensional structures, aided by the ribosomal proteins, to produce functionally active ribosomal subunits. The two subunits associate with one another to produce a 70S ribosome, with the space between them forming three transfer RNA (tRNA) substrate-binding sites. The manner in which tRNAs bind to and move through the ribosome forms the essence of the translation process.

Protein synthesis on the ribosome occurs in the three main phases of initiation, elongation, and termination. Elongation is an iterative process and can itself be divided into the three steps of tRNA selection, peptide bond formation, and translocation. During each elongation cycle, a tRNA substrate moves sequentially through three tRNA-binding sites, designated A (for acceptor or aminoacyl), P (for peptidyl), and E (for exit). To enter the elongation cycle, an aminoacyl-tRNA must be selected by the ribosome in accordance with the particular messenger RNA (mRNA) codon triplet present in the A site. This is the rate-limiting step of the elongation cycle, as the

ribosome must discriminate the correct, or cognate, aminoacyl-tRNA from the intracellular pool of much more numerous near-cognate and noncognate aminoacyl-tRNAs. No option exists other than to randomly sample a large number of aminoacyl-tRNAs for each codon. Successful selection of an aminoacyl-tRNA is followed by peptide bond formation, in which the growing nascent polypeptide chain is transferred from the peptidyl-tRNA in the P site to the aminoacyl-tRNA now stably bound in the A site. This leads to hybrid tRNA-binding states, with peptidyl-tRNA in the 30S A site and the 50S P site (the so-called A/P state) and deacyl-tRNA in the 30S P site and 50S E site (the P/E state). Hybrid states formation is accompanied by a relative rotation of the two ribosomal subunits. To advance to the next codon, the ribosome then undergoes a translocation step, during which the tRNA substrates move their anticodon ends in concert with mRNA on the 30S subunit to adopt the classical tRNA-binding states (P/P and E/E). This movement is accompanied by a reversal of subunit rotation back to the ground state, producing a vacant A site that is now ready for the next cycle of tRNA selection programmed by the next mRNA codon.

It is an axiom of the RNA world hypothesis that the prebiotic ribosome was composed entirely of RNA and carried out each of the steps of protein synthesis in a protein-independent manner. Even after 4.5 billion years of evolution, the ribosome retains the ability to carry out each of the elongation steps without added protein factors. The enzymatic activity of the ribosome, peptide bond formation, is catalyzed by a peptidyl-transferase active site that is still composed of rRNA. The chemical step of peptide bond formation is extremely fast, and evolutionary processes have not produced protein factors

to accelerate it. However, all organisms produce protein factors that greatly enhance the rates of the previous and subsequent steps, tRNA selection and translocation.

While free aminoacyl-tRNAs will bind to the ribosome in a codon-dependent manner *in vitro*, they are delivered to the ribosome *in vivo* as part of a ternary complex with a G-protein called elongation factor Tu (EF-Tu) and guanosine triphosphate (GTP). This incorporation of a GTPase protein factor into the kinetic pathway allows an additional discrimination or substrate-proofreading step, thereby greatly increasing the accuracy of tRNA selection. Translocation can also occur in the absence of exogenous factors, albeit very slowly. *In vivo*, cells greatly accelerate this reaction using second G-protein called EF-G. Thus, EF-Tu exists primarily to greatly enhance decoding accuracy by providing a proofreading mechanism, and EF-G accelerates translocation that would otherwise be unacceptably slow for the demands of the modern cell. One striking observation is the similarity in the overall shape of the EF-Tu–aminoacyl-tRNA–GTP ternary complex and EF-G, and the way in which they interact with the ribosome (Figure 1).

EF-Tu and Initial Selection

The very first event in tRNA selection is a codon-independent step termed initial binding. Cognate ternary complexes of EF-Tu–aminoacyl-tRNA–GTP undergo initial binding in competition with the more numerous noncognate and near-cognate complexes. This binding state is highly labile and has not been observed directly by cryo-electron microscopy (cryo-EM) or X-ray crystallography and has been detected solely by kinetic measurements. As this step occurs prior to codon–anticodon interaction, it does not contribute directly to tRNA discrimination.

After initial binding is initial recognition, wherein the aminoacyl-tRNA samples the codon in the A site. Noncognate aminoacyl-tRNAs are rejected at this step, while cognate aminoacyl-tRNAs (and less efficiently, near-cognate aminoacyl-tRNAs) adopt a stable binding state referred to as the A/T state, in which aminoacyl-tRNA occupies the 30S A site while remaining bound to EF-Tu. The ribosome contributes directly

to codon recognition by employing an induced fit mechanism, where the stereochemistry of codon–anticodon base pairing is precisely monitored by specific interactions with 16S rRNA residues. Of particular importance are those involving residues G530, which flips from the *syn* to the *anti* configuration, and A1492/A1493, which flip out from their stacked position in helix 44. C1054 also interacts with the codon–anticodon helix. These conformational changes place these residues in position to fit into the minor groove of the three-base-pair helix formed by the mRNA codon and the aminoacyl-tRNA anticodon (Figure 2(b)). The binding energy of these interactions induces a global conformational change in the 30S subunit from an open to a closed form that accelerates the forward steps of decoding. Because the non-A-form geometry of their codon–anticodon complexes is less effective at stimulating domain closure than cognate ones, near-cognate aminoacyl-tRNAs are usually rejected during initial recognition. Mutations perturbing the equilibrium of this open–closed transition, such as those producing changes in 16S rRNA, ribosomal proteins S4, S5, or S12, can either increase or decrease decoding accuracy.

Binding of aminoacyl-tRNA simultaneously to EF-Tu and the codon on the 30S subunit in the A/T state requires a 30° bend in the tRNA body in comparison to its configuration when bound to the ribosome in the A/A state (Figure 2(b)) or in complex with EF-Tu free in solution. The binding energy of codon recognition is used both to drive 30S subunit domain closure and to induce this bend. A G24A base substitution in the elbow region of tRNA^{Trp}, which is expected to facilitate this bending, accelerates both the initial recognition and proofreading rate constants. This results in misreading of UGA codons as UGG (Trp) codons.

EF-Tu and GTP Hydrolysis

After codon recognition and domain closure, the stable A/T-binding state of aminoacyl-tRNA activates the GTPase activity of EF-Tu. Near-cognate complexes do not effectively induce GTPase activation and have a greater likelihood of being released prior to GTP hydrolysis. Once GTP hydrolysis occurs, EF-Tu adopts a conformation that is incompatible with binding

Figure 1 Elongation factors Tu and G interact with the ribosome in similar fashions. (a) The EF-Tu (light pink) delivers aminoacyl-tRNA (dark pink) to the A site of the ribosome as a ternary complex with GTP. (b) EF-G (blue) binds to the ribosome to promote translocation. In both panels, only the 30S ribosomal subunit (cyan) is shown, with the 50S subunit omitted for clarity. P-site (green) and E-site (orange) tRNAs are shown.

either the ribosome or aminoacyl-tRNA and is released as EF-Tu-GDP. Once free of EF-Tu, aminoacyl-tRNA cannot return to the A/T state, and in this way GTP hydrolysis kinetically drives decoding forward. Perhaps surprisingly, the ribosome does not take advantage of the 350-fold difference in thermodynamic stability of cognate versus near-cognate codon-anticodon complexes in tRNA discrimination, because GTP hydrolysis occurs long before binding equilibrium is reached.

How codon recognition stimulates GTPase activation is not entirely clear, given the distance (some 80 Å) between the decoding site on the 30S subunit and the GTPase active site of EF-Tu (Figure 3). A large number of ribosomal components interact with EF-Tu or aminoacyl-tRNA in the A/T state and it is difficult to determine which ones are responsible for activating GTPase differentially in response to cognate and near-cognate ternary complexes. One ribosomal component frequently implicated is 50S ribosomal protein L7/L12, which is present as a tetramer or hexamer, depending on the bacterial species

(L7 is an acetylated form of L12). The L7/L12 tetramer/hexamer forms a stalk protruding from the ribosome and is conformationally dynamic, and, therefore, has been poorly disordered in ribosome X-ray crystal structures. This stalk is thought to recruit ternary complex to the ribosome, and depletion of the stalk eliminates GTPase activation. Ribosomal protein L11, near the base of the stalk and close to the GTPase active site of EF-Tu, also forms part of the binding site for the antibiotic thiostrepton. On the 30S subunit, aminoacyl-tRNA in the A/T state makes direct contact with ribosomal protein S12. A large amount of genetic data implicates this protein in the decoding process, with some suggesting a role for this contact in GTPase activation. As no single component can monitor codon recognition and interact with the GTPase active site simultaneously, activation must result from the cooperative action of multiple ribosomal elements.

However GTPase activation occurs, GTP hydrolysis by EF-Tu is controlled by a hydrophobic gate, in which Val20

Figure 2 Codon recognition occurs in the ribosomal A site during tRNA selection. (a) 16S rRNA bases G530, C1054, A1492, and A1493 (cyan) change conformation, as part of an induced fit mechanism, to monitor Watson-Crick base pairing between the anticodon bases (blue) and the mRNA codon bases (green). Cognate codon recognition leads to a global conformational change in the 30S subunit. (b) Bending of aminoacyl-tRNA in the A/T state. This bending allows simultaneously codon recognition and interaction with EF-Tu. Base pairing between tRNA anticodon and mRNA codon occurs in the same manner in both the A/T (prior to proofreading) and A/A states (after proofreading and accommodation).

Figure 3 Details of ribosome interaction with EF-Tu-aminoacyl-tRNA-GTP in the A/T state. The acceptor helix of aminoacyl-tRNA interacts with ribosomal protein S12 (red). EF-Tu (blue) interacts with the sarcin-ricin loop (SRL) of 23S rRNA (tan). Kirromycin is shown as pink spheres, with GDP as orange spheres, while mRNA and tRNAs are colored green and cyan, respectively. Most of the ribosome is omitted for clarity.

and Ile60 move to allow putative catalytic residues Gly83 and His84 access to GTP. G2661 in the sarcin–ricin loop of 23S rRNA may hold His84 in an inactive conformation until cognate-codon recognition is signaled. Upon GTP hydrolysis, EF-Tu–GDP is released, leaving the aminoacyl-tRNA free to move into the A/A state in a process referred to as accommodation. Free EF-Tu–GDP then forms a complex with the elongation factor EF-Ts, GDP is exchanged for GTP, and EF-Tu–GTP reenters the pool of ternary complexes with aminoacyl-tRNA.

Substrate Proofreading

The ribosome achieves accuracy of tRNA selection by employing two sequential steps, the initial selection step described above and a substrate-proofreading step, kinetically separated by the irreversible hydrolysis of GTP by EF-Tu. The occasional near-cognate aminoacyl-tRNA that slips through initial selection to form a stable complex with the ribosome is usually rejected at this point. Although the mechanistic details of proofreading remain to be established, substrate proofreading by the ribosome is distinct from the product-proofreading mechanism utilized by DNA polymerases, in that it results in the rejection of incorrect substrates prior to, rather than after, polymerization. This two-step filtering mechanism greatly enhances the accuracy of tRNA selection, with the overall selectivity being the product of the selectivity of the individual steps.

An aminoacyl-tRNA that successfully passes through the proofreading step adopts the A/A classical tRNA-binding state in a process termed accommodation. In the A/A state, the acceptor end of the aminoacyl-tRNA is positioned in the peptidyltransferase active site on the 50S ribosomal subunit. Once peptide bond formation occurs, the ribosome has committed itself to incorporation of this amino acid into the growing polypeptide chain.

EF-G and Translocation

After tRNA selection and peptide bond formation, the ribosome undergoes a large conformational rearrangement, a relative rotation of the 30S and 50S subunits of about 6–10°. This rotation places the tRNAs in hybrid-binding states, in which the CCA ends of the A-site and P-site tRNAs have moved into the P and E sites, respectively, on the 50S subunit, while the anticodon ends remain in the A and P sites, respectively, on the 30S subunit. These hybrid states are adopted sequentially, with the P/E (30S P site/50S E site) hybrid state forming before the A/P (30S A site/50S P site) hybrid state. The next step is the concerted movement of the mRNA by one codon and the anticodon ends of the tRNAs into the 30S subunit P and E sites, and the reversal of the ratcheted state of the ribosome. This step is called translocation, and occurs spontaneously on the ribosome. The spontaneous reaction is very slow, and is accelerated about 50 000-fold by the activity of EF-G. Although EF-G hydrolyzes GTP, this catalytic activity is not absolutely essential for translocation, as EF-G–GDP or EF-G with a nonhydrolyzable GTP analog will also promote the reaction, albeit at a 50–100-fold lower rate. Instead, GTP hydrolysis actually precedes translocation and induces a conformation of EF-G that stabilizes an ‘unlocked’ configuration of the ribosome.

The unlocked configuration of the ribosome is associated with multiple structural changes, including the aforementioned ratcheting motion of the two subunits, a movement of the L1 stalk on the E-site side of the ribosome, and formation of the P/E hybrid tRNA-binding state. These three events are only loosely coupled to one another, and the role of EF-G may be to couple these events in order to make the ribosome competent for translocation. After translocation and release of EF-G–GDP, the ribosome reverts to the locked configuration, but with tRNAs now in the classical states (P/P and E/E), and is ready to select the next aminoacyl-tRNA.

Reverse translocation, with movement of tRNAs back into the hybrid states, occurs spontaneously in the absence of EF-G, indicating that movement of tRNAs in either direction through the ribosome in the unlocked configuration occurs by diffusion. EF-G favors movement in the forward direction, by preventing movement in the backward direction. This is consistent with the EF-G–ribosome co-crystal structure, which shows loop I of domain IV of EF-G stabilizing peptidyl-tRNA in the posttranslocation state via interactions with the minor groove of the codon–anticodon mini-helix in the P site (Figure 4). Thus, EF-G acts as a Brownian ratchet to prevent backward movement of the tRNA–mRNA complex.

EF-G–Ribosome Interactions

X-ray crystal structures of isolated EF-G or the EF-Tu–aminoacyl-tRNA–GTP ternary complex reveal an overall resemblance in shape, not only suggesting a common evolutionary origin of the two factors but also reflecting a similarity in the way they interact with the ribosome. This latter point is most obvious in cryo-EM reconstructions and X-ray crystal structures of these factors bound to the ribosome (refer once again to Figure 1). In comparison to EF-Tu, which adopts radically different conformations in the EF-Tu–aminoacyl-tRNA–GTP ternary complex and the EF-Tu–GDP binary complex, EF-G undergoes only limited changes in conformation. Domain III is particularly dynamic in its position relative to the rest of the factor, and was disordered in early EF-G crystal structures. Many mutations conferring resistance to fusidic acid, an antibiotic that freezes EF-G on the ribosome after GTP hydrolysis, are located at the interface between domain III and the rest of EF-G, suggesting that movement of domain III is important for EF-G function. EF-G–GTP binds to the ratcheted configuration of the ribosome in the pretranslocation state, with individual contacts occurring in an as yet unknown sequence. Like EF-Tu, EF-G undergoes a GTPase activation step.

After GTP hydrolysis and translocation, the ribosome returns to the nonratcheted, locked configuration with tRNAs in the classical binding states (P/P and E/E). A high-resolution X-ray crystal structure of this posttranslocation complex reveals many of the details of EF-G–ribosome interaction (Figure 4). Domain III simultaneously contacts the sarcin–ricin loop on the 50S subunit and ribosomal protein S12 on the 30S subunit. These contacts are probably essential, as EF-G lacking domain III has greatly decreased GTPase activity and is defective in translocation. Further, by interacting simultaneously with both subunits, domain III may assist EF-G in distinguishing between the locked and unlocked configurations of the ribosome.

Figure 4 Details of EF-G–ribosome interactions after translocation. EF-G (blue) domain IV interacts with peptidyl-tRNA in the P site (cyan), while domain III interacts simultaneously with ribosomal protein S12 (red) and the sarcin-ricin loop (SRL) of 23S rRNA (tan). The C-terminal tail of ribosomal protein S13 (red) also interacts with the peptidyl-tRNA anticodon helix in the posttranslocation state (compare its position in [Figure 3](#)). Fusidic acid is shown as pink spheres, GDP as orange spheres, while mRNA and tRNAs are colored green and cyan, respectively. Most of the ribosome is omitted for clarity.

EF-G prevents reverse translocation primarily through its interactions with the 30S subunit. Domains III and IV, whose positions are spatially analogous to that of the aminoacyl-tRNA moiety of the EF-Tu–aminoacyl-tRNA–GTP ternary complex, sterically block backward movement of the tRNA–mRNA complex. Domain III interacts extensively with ribosomal protein S12, while domain IV interacts directly with both ribosomal protein S13 and peptidyl-tRNA in the P site. These interactions are accompanied by an altered conformation of the extended tail of S13, which itself now also interacts with the anticodon helix of peptidyl-tRNA ([Figure 4](#)). Mutations affecting ribosomal protein S12 or chemical modification of either S12 or S13, all stimulate spontaneous translocation, suggesting that EF-G stimulates translocation, in part, through its interaction with these proteins.

EF-G and Ribosome Recycling

In addition to its role in the elongation cycle, EF-G also participates in dissociation of the 70S ribosome into 30S and 50S subunits following translation termination. This is done in concert with ribosome recycling factor (RRF). RRF binds to the ribosome with deacylated tRNA in the P/E state. Following the action of EF-G, which requires hydrolysis of GTP and release of inorganic phosphate, the subunits dissociate and IF3 binds to the 30S subunit. The presence of IF3 prevents reassociation of the 30S and 50S subunits and promotes the release of deacylated tRNA and mRNA prior to the formation of a translation initiation complex. In mitochondria, two distinct EF-G proteins carry out translocation and recycling. Although complexes of 70S ribosomes and RRF have been solved by X-ray crystallography, posttermination complexes with both RRF and EF-G have not.

Conclusion

During the elongation phase of protein synthesis, tRNA selection and translocation are regulated by the action of two

GTPases that bind to the same region of the ribosome. In the case of tRNA selection, EF-Tu delivers aminoacyl-tRNA in a ternary complex with GTP to the A site of the ribosome. This factor kinetically divides tRNA selection into the two steps of initial recognition and proofreading by the irreversible hydrolysis of GTP. The use of two sequential steps results in an overall accuracy of decoding that is the product of the accuracy of the two individual steps. In the case of translocation, EF-G complexed with GTP stabilizes or induces an unlocked configuration of the ribosome. This unlocking entails a relative rotation of the 30S and 50S subunits, coincident with the formation of hybrid tRNA-binding states resulting from peptide bond formation. In the unlocked configuration, tRNAs and mRNA are capable of spontaneous movement through the ribosome. Although the spontaneous reaction is inherently reversible, the presence of EF-G in the ribosomal A-site prevents the backward movement of the tRNA–mRNA complex. Thus, EF-G acts as a Brownian ratchet to shift the equilibrium of the translocation reaction in the forward direction. It is, in part, through the use of these two protein factors that the ribosome achieves its remarkable accuracy and speed.

Glossary

A site The ribosomal binding site for the incoming aminoacyl transfer RNA (tRNA), whose covalently bound amino acid will be the next addition to the growing peptide chain.

Decoding The multistep process in which the ribosome determines whether an incoming tRNA carrying the next amino acid to be added is correct or incorrect. If incorrect, the tRNA is rejected.

E site The ribosomal binding site for the exiting tRNA, which has already donated its amino acid to the peptide chain.

Messenger RNA (mRNA) A transient RNA copy of the DNA instructions coding for the protein to be synthesized, hence the genetic template for protein synthesis on the ribosome.

P site The ribosomal binding site for the peptidyl tRNA, which is covalently attached to the growing peptide.

Peptidyl transfer The chemical reaction between the free amino group of an amino acid and the esterified

carboxy terminus of a peptide, which results in the formation of a new peptide bond. The RNA-based ribosomal catalyst of this reaction is referred to as peptidyl transferase.

Ribosome The macromolecular complex of several large RNAs and about 50 small proteins that performs translation.

Ribozyme An enzyme which is made of RNA rather than protein.

Transfer RNA (tRNA) The substrate for the ribosome. One end of the L-shaped tRNA base pairs with mRNA, which allows ribosomal decoding, while the other end bears a covalently attached amino acid, which is added to the growing protein in the ribosome.

Translation The synthesis of protein, as determined by a messenger RNA template; it is catalyzed by ribosomes and ribosome-associated proteins, such as the initiation, elongation, and termination factors.

Translocation The movement of tRNAs and associated mRNA through the ribosome, from A site to P site, and from P site to E site.

Ribosome Function

Overview

In all organisms, template-directed protein synthesis is performed by the ribosome. The ribosome translates genetic information contained within its template, messenger RNA (mRNA), by joining amino acids carried by its substrates, transfer RNAs (tRNAs). The mRNA template is a linear sequence of nonoverlapping, three-nucleotide codons, each of which codes for a single amino acid to be added to the protein chain. There are 20 different kinds of amino acids, which become linked to tRNAs specific for each particular amino acid. The tRNAs are fairly large, L-shaped macromolecules with functionally important ends (Figure 1). One end, the aminoacyl end or 3' CCA terminus, is the site of covalent attachment of the amino acid. The other end features a three-nucleotide anticodon that forms base-pairing interactions with a complementary mRNA codon while in the ribosome.

The ribosome contains three distinct binding sites for substrate tRNAs, as well as a long path for mRNA (Figure 1(c)). The three tRNA-binding sites are named after the state of the tRNA that will be found at that site. The A site binds an incoming aminoacyl tRNA, the P site contains the peptidyl tRNA, and the E site contains an empty or exiting tRNA, which is deacylated. The ribosome also has binding sites for the many protein translation factors required for the rapid *in vivo* rates of protein synthesis.

Activities of the Ribosome

After the ribosome binds mRNA and initiator tRNA during translation initiation, new proteins are actually synthesized

during the elongation cycle of translation. The cycle begins with a peptidyl tRNA in the P site, and an empty A site. The elongation factor (EF)-Tu delivers a candidate aminoacyl tRNA to the A site, and the ribosome determines whether the candidate tRNA is a correct (or cognate) tRNA or one of the more numerous incorrect (noncognate) tRNAs. This gate-keeping function, known as 'decoding', is crucial for maintaining the accuracy of translation and thus of the genetic information contained in DNA.

Once an incoming aminoacyl tRNA has been accepted in the A site, its amino acid must be added to the peptide chain attached to the P-site tRNA. A new peptide bond is formed when the α -amino group of the aminoacyl-tRNA in the A site attacks the C-terminal carbonyl of the growing peptide attached to P-site tRNA. Peptide bond formation results in transfer of the peptide chain to the A-site tRNA and deacylation of P-site tRNA. Subsequent coordinated movement of the tRNA and mRNA relative to the ribosome (from right to left in Figure 1(c)), catalyzed by EF-G, restores a peptidyl tRNA in the P site and places a deacylated tRNA in the E site. During translocation, the ribosome must prevent slippage of the tRNA substrates relative to the mRNA template, which would alter the reading frame on mRNA and result in the synthesis of an incorrect and usually prematurely terminated protein. Translation terminates when a stop codon in the mRNA is reached. Stop codons are not recognized by tRNAs, but by protein release factors (RFs) which catalyze the hydrolysis of the peptidyl tRNA and release of the nascent protein.

Although EF-Tu and EF-G are required for the rapid *in vivo* rates of elongation, it is important to note that decoding, peptide bond formation, and translocation are all inherent

Figure 1 (a) Schematic view of a tRNA, the substrate of the ribosome. (b) Three-dimensional cartoon view of the structure of a tRNA. (c) Schematic view of a translating ribosome. Three amino acids (circles numbered 1–3) have already been joined to form the nascent peptide chain, whose C-terminal end is covalently attached to the tRNA in the P site. The next amino acid to be added (circle 4) is attached to a tRNA, which has just bound the ribosomal A site. A deacylated tRNA (left rectangle) is in the E site and will soon exit the ribosome. Vertical triplet bars represent codons in the mRNA, which base-pair to complementary anticodons in the tRNAs. The tRNA–mRNA complex moves through the ribosome from right to left, with each tRNA donating its covalently attached amino acid to the growing peptide chain as it passes through the peptidyl transferase site.

functions of the ribosome; they can be performed by the ribosome without the aid of EFs.

Ribosome Structure

Subunit Organization and Nomenclature

Ribosomes are large and complex enzymes: the simplest ribosomes from bacteria have a mass of some 2.5 million Da. All ribosomes consist of two loosely associated subunits of unequal size. In the bacterial ribosome, the large subunit is denoted the 50S, the small subunit 30S, and the entire ribosome 70S, according to their rates of sedimentation during ultracentrifugation. The bacterial small subunit consists of the 16S ribosomal (rRNA), which is approximately 1500 nucleotides, and around 20 small proteins (named S1, S2, etc.). The large subunit contains the 23S rRNA (~2900 residues), the 5S rRNA (~120 residues), and around 30 proteins (L1, L2, etc.). Eukaryotic ribosomes are even more massive, with the 60S large subunit (with 5S, 28S, and 5.8S rRNAs plus proteins) and the 40S small subunit (with 18S rRNAs plus proteins) making up the 80S ribosome.

In addition, eukaryotic cells contain mitochondrial ribosomes, and plant cells may also have chloroplast ribosomes.

In all ribosomes, the large subunit interacts with the CCA end of the tRNAs and contains the active site (the peptidyl transferase center (PTC)) which catalyzes peptide bond formation. The small subunit binds the anticodon end of the tRNAs, both monitoring (during decoding) and maintaining (during translocation) the tRNA–mRNA base-pairing interactions.

The Road to Ribosome Structure

The great size and complex composition of ribosomes were enormous barriers to efforts to determine the structural basis of ribosome function. The ribosome size is inconvenient for structural biology: it was, until recently, too large for X-ray

crystallography, but also rather too small for cellular electron microscopy (EM) methods. Many genetic, biochemical, and biophysical methods were developed over the years to probe ribosome structure, and divide and conquer strategies were able to determine high-resolution structures of small fragments of the ribosome, all of which yielded large amounts of useful data. However, the ultimate goal of revealing the chemical basis of protein synthesis would require visualizing intact ribosomes and ribosomal subunits at the high resolution possible.

Single particle EM led the way in the structural characterization of ribosomes. First, very low resolution images (~40 Å) from negatively stained EM collected in the 1970s showed the shapes and large structural features of the subunits. Then a big step forward occurred in 1995 when Joachim Frank and co-workers, using images of the ribosome suspended in vitreous ice (cryo-EM), visualized the ribosome at 25 Å. Shortly afterward, both the Frank and van Heel groups were able to identify the tRNAs in complex with the ribosome at similar resolution. Resolutions of EM reconstructions gradually improved, but it was X-ray crystallography that provided the decisive breakthroughs to atomic detail.

Crystals of ribosomes had been around for decades, the first being of a bacterial 50S reported by Wittmann, Yonath, and colleagues in 1980. In 1987, the Garber group in Puschino, Russia was the first to report 30S and 70S crystals. However, the technology and know-how to determine the structures of these large asymmetric molecules was lacking. By the late 1990s, this had all changed. The Steitz and Moore groups successfully calculated maps of the large subunit from *Haloarcula marismortui* at 9 Å resolution in 1998. By 1999, this was improved to 5 Å, and Ramakrishnan simultaneously reported a 5-Å structure of the small subunit from *Thermus thermophilus*. By the next year, atomic resolution was achieved for both crystal forms; these structures were completely built. The Yonath group also released a small subunit structure at the same time and at comparable resolution, and later determined the structure of a bacterial large ribosomal subunit. Suddenly, almost

all of the details of ribosomal architecture were clear, enabling many fundamental new insights into the structural basis for translation mechanisms.

The subunit structures were the culmination of a vast amount of work, but rather than capping off the field, they sparked a new dawn in ribosome study by structural, biochemical, single molecule, and biophysical techniques. In crystallography studies, these crystal forms of the ribosomal subunits were used to produce a myriad of co-crystal structures to study decoding, peptide bond formation, and antibiotic action. The subunit structures were also used to derive the phases required to solve structures of the 70S ribosome. The *T. thermophilus* 70S structure was determined to moderate resolution by the Noller and Yusopov group and then to high resolution by the Ramakrishnan group. The later 70S crystal form was subsequently used by Noller, Steitz, and Yusupov, while the Cate group concentrated on *Escherichia coli* ribosomes. Furthermore, the flexible areas of the ribosome which were not easily seen in some of these crystal structures, such as the L1 and L7/L12 stalks of the 50S subunit, have been determined in isolation to high resolution. More recently, structures of the ribosome have been solved in complex with translation factors, providing a major breakthrough in understanding how these work. Finally, the Ban and Yusupov groups achieved the next big step by determining crystal structures of the eukaryotic small subunit and 80S ribosome.

Although cryo-EM lost the race to atomic structures, it continues to be a relevant and useful tool for ribosome study, benefiting greatly from the X-ray structures to allow molecular interpretation of EM reconstructions. The achievable resolution has improved to near X-ray standards, and it is very powerful to visualize the many transient conformations required for ribosome function. In all, we now have a very detailed picture of the structure of the ribosome and how the ribosome changes to perform its many tasks.

General Features of Ribosomal Architecture

The overall architecture and composition of the ribosome and its functional centers reveal it to be essentially an RNA-based machine. The shape of both subunits is determined by the RNA

component: only one of the landmark features visible at low resolution (the L7/L12 stalk) is composed only of protein (Figure 2). Moreover, the overall distribution of the proteins is not uniform: the proteins are concentrated on the back and sides of the subunits, away from the most functionally important regions at the subunit interface. The protein component is also concentrated on the surface, rather than buried in the middle of the subunits; the ribosome thus literally has an RNA core. Many of the proteins contain both a globular component on the periphery of the subunits and one or more narrow extended peptide tails that penetrate deeply into crevices of the RNA core. Proteins are found to interact with RNA multistem junctions and tight bends in the RNA, which suggests particular functional roles in subunit assembly, in agreement with biochemical data.

It makes good sense that the ribosome is an RNA-based enzyme, whereas most other enzymes are made entirely of protein. After all, if proteins were made by a hypothetical ribosome composed entirely of protein, it would be hard to imagine how this protein-only ribosome could have evolved. An RNA-based ribosome solves this chicken-and-egg problem and fits well with speculations about an RNA world preceding the existence of large proteins and DNA.

There is one functionally important difference between the large-scale architectures of the 30S and 50S subunits. While the secondary structure domains of the 23S rRNA interact closely to form a single, nearly hemispherical mass, the 16S rRNA secondary structure domains are for the most part independent globular entities – true three-dimensional domains – that have relatively few interactions with each other. One domain of the 16S rRNA constitutes the head, another the platform, and another the bulk of the body. This architecture allows required conformational changes in the small subunit, such as rotation of the head which accompanies translocation. By contrast, the biggest movements of the large subunit are in peripheral helices (L1 stalk, Helix 69) or protein features (L7/L12 stalk).

In addition to information specifically about ribosome function, these structures provide an enormous boost to the understanding of RNA-protein, RNA-ion, and RNA tertiary interactions, since they vastly expand the database of known

Figure 2 The three-dimensional structure of the ribosome. The 30S subunit, tRNAs and mRNA are shown in panel (a), the 50S subunit and the same tRNAs are shown in panel (b), and the 70S ribosome with tRNAs and mRNA is shown in panel (c). Landmarks are indicated in each panel. DC denotes decoding center, CP denotes central protuberance, and PTC denotes peptidyl transferase center. Figure 3 The kink turn (a) and the A-minor motif (b) are two RNA packing features seen repeatedly in the ribosome.

RNA structure. Two principles of RNA higher-order structure which were revealed are the A-minor motif and the kink turn (Figure 3). The A-minor motif is a common strategy for packing RNA helices, whereby patches of adenine residues pack their bases and 2' OH moieties against the minor groove of another RNA helix. Four different classes of this A-minor motif were defined, some of which had been previously observed in other structures. The kink turn is a common RNA structure of about 15 nucleotides which contains a kinked phosphodiester backbone and a sharp turn of an RNA helix. The kink turn is predictable from sequence information and is stabilized by interactions with proteins.

The Small Subunit and Decoding

A principal role played by the small subunit is the binding of mRNA and appropriate tRNAs (Figure 2(a)). The mRNA wraps around what would be the neck of the small subunit, between the head and the body. The mRNA pathway becomes a tunnel when noncovalent interactions between the head and shoulder domains form a so-called latch. The mRNA enters this tunnel behind the shoulder of the small subunit, and the nearby proteins S3 and S4 which form the entrance to the tunnel have been implicated in helping resolve secondary structure in the mRNA, thus imparting helicase function to the ribosome as part of translocation. The path then leads to the A site, responsible for decoding (see below), then to P and E sites. There is a turn in the mRNA pathway between the A and P sites which delineates the border of these sites, and the mRNA structure here is sharply kinked, the kink stabilized by a magnesium ion. The kink is thought to allow A and P site bound tRNAs to interact with adjacent nucleotides in the mRNA, prevent slippage of mRNA, and define the appropriate reading frame. Overlapping with and following on from E site, the mRNA passes the very 3' end of the 16S rRNA with which during the initiation phase of translation the Shine Delgarno sequence in the mRNA forms a helix. The mRNA then emerges from the 30S adjacent to the platform. Special functional sequences in the mRNA can interact with the ribosome near the platform to influence translation.

During elongation, incoming aminoacyl tRNAs bind the 30S A site, which is also called the 'decoding center'. The rate of protein synthesis is about 20 amino acids added per second, and there are substantially more incorrect (noncognate) aminoacyl-tRNAs present than correct (cognate) ones, so the ribosome must very quickly and robustly detect whether the

tRNA is appropriate to use. The 30S subunit plays a crucial role in tRNA selection by directly monitoring base-pairing interactions between the tRNA anticodon and the mRNA codon. In the presence of a cognate A-site tRNA, conformational changes occur in 16S rRNA residues A1492, A1493, and G530 (*E. coli* numbering), conserved elements of the head (helix 34) and body (the 530 loop), to sense the correctness of the codon-anticodon interaction. A1492, A1493, and G530 swing out and dock into the minor groove of the A-site codon-anticodon minihelix to test whether the geometry of the minihelix is correct (Figure 4). Monitoring geometry of the minihelix is an elegant way to determine whether the tRNA anticodon matches the codon, as it relies on the correctness of the base pair only, not of the sequence. The pairing is most stringently monitored at the first two positions of the codon, whereas the third wobble position has more flexibility. If the codon-anticodon matching is deemed correct, a more global conformational change occurs, moving the shoulder region of the 30S toward the decoding center. This larger-scale conformational change from an open to a closed form is involved in the signal for guanosine triphosphate (GTP) hydrolysis by EF-Tu, the EF that delivers the incoming candidate tRNAs to the A site (see below).

Many antibiotics (streptomycin, spectinomycin, tetracycline, hygromycin B, pactamycin, and edeine) bind to the 30S. Some, such as tetracycline, act by preventing binding of tRNA substrate. Interestingly, binding of error-inducing antibiotics of the aminoglycoside family causes some of the conformational changes seen in decoding, such as the swinging out of A1492-3. These aminoglycosides were thus proposed to induce miscoding by stabilizing a conformation very similar to the closed form adopted during normal translation.

The Large Subunit and Peptide Bond Formation

The large ribosomal subunit catalyses the key chemical event in protein synthesis, peptide bond formation. The catalytic active site is in the bottom of a deep cleft, open on one side to allow binding of tRNA substrates. The PTC leads to a long tunnel, through which the nascent peptide chain travels to leave the ribosome on the back side of the large subunit.

Although the ribosome is vast, all of the key elements required to catalyze the peptidyl transferase reaction are within ~ 15 Å of the reactive atoms. As with all enzymes, substrate positioning is vital for reaction. Precise substrate positioning is achieved when the proper binding of the 3' terminal

Figure 4 The decoding center of the 30S subunit. When the decoding center (a) is bound by a cognate tRNA (b) 16S residues A1492, A1493, and G530 rearrange to monitor the mRNA–tRNA interaction. (c–e) The specific interaction of the decoding center with the codon and anticodon at the three base pairs. CCA sequence of aminoacyl-tRNA to the A site of the PTC induces a reaction-competent conformation of the PTC and the peptidyl-tRNA, bound to the P site. The reactive α -amino group is oriented for nucleophilic attack by hydrogen bonds to the N3 of A2451 of 23S rRNA and the 2' OH of A76 of the peptidyl-tRNA. The ribosome does not appear to employ a metal ion or provide a near-neutral group for general acid–base catalysis. Rather, it now seems likely that the 2' hydroxyl of the peptidyl-tRNA's final nucleotide, A76, abstracts a proton from the alpha amino group of the aminoacyl-tRNA in a proton-shuttling mechanism (Figures 5(b) and 5(d)). In addition, the highly polarized transition state appears to be stabilized by a polar water molecule which is precisely positioned by the ribosome to act as a oxyanion hole. No ribosomal protein acts directly in this reaction, making the ribosome a ribozyme, but ribosomal proteins (L10e in archaea and L16 and L27 in bacteria) are nearby and help binding of tRNAs. Although this catalytic mechanism is supported by many studies, a caveat remains, as one set of experiments using cell extracts appears to show that a 2'-deoxy-A76 tRNA is competent for use in protein synthesis. The reasons for this discrepancy need to be clarified.

Although the ribosome is asymmetric, there exists a pseudo twofold symmetry at the heart of the PTC, relating the 50S A and P sites. This is likely a relic from when the proto-ribosome was formed by a duplication event of ~ 100 nucleotides of RNA, which first allowed bringing together of two similar substrates. The modern 23S rRNA results from subsequent asymmetric expansion of the nucleotide sequence through large insertion events.

The large ribosomal subunit is a common target for antibiotics. Although these antibiotics work in many different ways, two common themes seem to be prevention of tRNA binding (e.g., puromycin and sparsomycin) and interference with the nascent peptide chain in the exit tunnel (the macrocyclic family). Understanding the molecular interactions of these compounds with the ribosome is of great use in rational design of improved antibacterial drugs.

The bulk of the 50S is monolithic and moves very little during protein synthesis. Two large protuberances, the L1 arm and the L7/L12, do move. The L7/L12 arm is made of the L10 RNA-binding site, L10, and four to six copies of protein L12 (L7 is a modified form of L12). This huge feature waves around, probably to help recruit incoming tRNAs and translation factors to the A site. The L1 protein and the helix of 23S rRNA bind to perform the complementary function, changing conformation to facilitate release of the deacylated tRNA from the E site.

The 70S Ribosome and Translocation

Although codon recognition and peptide bond formation are fundamentally functions of the small and large subunits, respectively, the subunits work together in the context of the full 70S ribosome throughout elongation to perform protein synthesis. The subunits are held together by subunit bridges made by every possible combination of interaction: RNA–RNA, RNA–protein, protein–protein, water-mediated, and ion-mediated interactions. The tRNAs must travel through the ribosome during protein synthesis, and although this is

Figure 5 The peptidyl transferase center (a) and the reaction it catalyzes (b). The mechanism likely involves the 2' hydroxyl group of the peptidyl-tRNA both orienting the nucleophilic alpha amino group (c) and accepting a proton during the breakdown of the reaction intermediate (d). Reproduced from Schmeing TM, Huang KS, Kitchen DE, Strobel SA, and Steitz TA (2005) Structural insights into the roles of the 2' hydroxyl of the peptidyl-tRNA and water in the peptidyl transferase reaction. *Molecular Cell* 20(3): 437–448.

catalyzed *in vivo* by EF-G, translocation is an intrinsic function of the ribosome. After peptide bond formation, the first step of translocation is a movement of the 3' ends of the tRNA from A to P and P to E sites of the 50S subunit, independent of the stationary anticodon ends. This step can initially occur with little change in the ribosome conformation. In the next step, the relative orientation of the subunits changes markedly, as a ~6–8 degree rotation or ratcheting motion occurs and the head domain of the 30S subunit moves substantially. To complete translocation, the anticodon end of the tRNAs and the mRNA shift in the 30S subunit, while the ribosome returns to the un-ratcheted state. These ratcheting and unratcheting movements necessitate shifting, rearrangement, or breaking and reforming of many of the intersubunit bridges, and the

strengths of the interactions at the start, intermediate, and end states of ratcheting must be exquisitely balanced to allow ratcheting when required, while also holding subunits together. Furthermore, the three tRNA substrates are intimately cradled by subunit bridges in the intersubunit space in such a way that relative movement of the subunits can effect translocation of the tRNAs. Fully defining the steps of translocation is a very active area of research, with cryo-EM and single particle work leading the way.

The Ribosome and Translation Factors

High-resolution crystal structures of the ribosome in complex with the translation factors required to catalyze the *in vivo* rates

of protein synthesis were the next frontier after the subunit and 70S structures. Some of these proteins, despite being quite large, fit smoothly into the crystal forms of the unliganded ribosome. This allowed determination of co-crystal structure with initiation factor 1, EF-P, RF I and II, and ribosome recycling factor. Of these, the structures provided greatest insight into the function of EF-P and RFI and II.

EF-P is a translation factor that, although not required in a minimal cell-free translation system, promotes peptide bond formation and is conserved in all kingdoms of life. The crystal structure of the 70S with EF-P and initiator tRNA in the P site shows that EF-P binds to an area of the ribosome between the classical P and E sites and shifts the conformation of the L1 arm (**Figure 6(a)**). EF-P is nestled up against the P-site tRNA and makes many interactions with it, including close to the aminoacyl end. However, the conformation of the P-site tRNA is the same in absence and presence of EF-P, and thus the role of EF-P is simply to stabilize the tRNA in a conformation competent to participate in peptide bond formation. It is not clear whether EF-P is used to aid the formation of just the first peptide bond, or of each peptide bond made.

At termination, class I RFs (RFI and RFII) bind to ribosomes which contain stop codons in the 30S A site and catalyze peptide release at the PTC (**Figure 6(a)**). A series of crystal structures shows how the RFs use specific interactions between the protein and the mRNA codon to distinguish stop codons from sense codons. In the 50S, each RF inserts a

conserved glycine–glycine–glutamine sequence into the PTC to hydrolyze the nascent peptide, perhaps through coordination of the nucleophilic water and/or product stabilization. Computational simulations using these crystal structures provide complementary insight into the release mechanism.

Many of the essential EFs, such as IF2, EF-Tu, EF-G, and RF3, are GTP-hydrolyzing enzymes, which have a conserved guanosine triphosphatase (GTPase) domain and all bind to the same location on the ribosome, called the GTPase factor binding site, which is adjacent to the A site. In all the 70S crystals reported prior to 2009, the ribosomal protein L9 from an adjacent ribosome in the crystal protruded from that ribosome and blocked the GTPase factor binding site (not shown in these figures). The Ramakrishnan group genetically removed L9 from the *T. thermophilus* ribosome and were then able to find several new crystal forms that allowed co-complexes of the ribosome with GTPase factors EF-G and EF-Tu.

EF-G is a large, 78-kDa protein that catalyzes translocation. EF-G is seen bound at the factor-binding site, interacting with both the 30S and 50S including the L7/L12 stalk. Its G-domain is bound near the Sarcin Ricin Loop of 23S rRNA, and its domain IV inserts into the decoding center (**Figure 6(c)**). There, domain IV makes critical interaction with both the mRNA codon and the tRNA in the P site which serve to ensure that the mRNA and tRNA move together in translocation.

EF-Tu is the GTPase factor that delivers incoming aminoacyl-tRNA to the A site. When EF-Tu and aminoacyl tRNA are

Figure 6 The 70S ribosome in complex with translation factors EF-P (a), RFII (b), EF-G (c), and EF-Tu (d). (e) GTP hydrolysis by EF-Tu is facilitated by the phosphate of 23S rRNA residue A2662, part of the sarcin ricin loop, helping His84 of EF-Tu to orient the reactive water molecule. Figure 7 The 80S ribosome from Baker's yeast. The extensions of rRNA specific to eukaryotes are shown in purple for the small subunit and red for the large subunit. Reproduced from Ben-Shem A, Jenner L, Yusupova G, and Yusupov M (2010) Crystal structure of the eukaryotic ribosome. *Science* 330(6008): 1203–1209, with permission from AAAS.

bound to the ribosome, the body of the aminoacyl tRNA is distorted, so that it can interact with both the decoding center and the factor-binding site, where EF-Tu sits (**Figure 6(d)**). This is necessary so that the anticodon–codon matching can be tested before GTP hydrolysis leads to release of EF-Tu and acceptance of tRNA. Cognate tRNA binding produces the changes at the decoding center and the movement of the shoulder domain (see above, The Small Subunit and Decoding), which, along with conformational changes in the tRNA and EF-Tu transfer the signal that a proper codon–anticodon match has been made to the GTPase center of EF-Tu. The GTPase center is interacting with the 23S rRNA, and a phosphate group of the 23S rRNA positions histidine 84 of EF-Tu to coordinate a water molecule for nucleophilic attack of GTP (**Figure 6(e)**). After GTP hydrolysis and Pi release, EF-Tu leaves the ribosome, and aminoacyl-tRNA can be rejected by a proofreading mechanism or accepted into the A site of the PTC.

Structures of Eukaryotic Ribosomes

The most recent breakthroughs in ribosome structure are crystal structures of the eukaryotic small subunit in complex with initiation factors from the Ban group and a structure of the yeast 80S ribosome from the Yusupov group. Eukaryotic ribosomes are significantly larger than prokaryotic ribosomes, possessing more proteins and expansion segments that enlarge the rRNA. The 80S structure, solved at 4.2 Å resolution, shows that the extra mass of the 80S is located at the periphery of both subunits, while the core which contains the active sites required for the universal functions of the ribosomes is more

similar to prokaryotes (**Figure 7**). In addition, this 80S was determined in a ratcheted state (see above), which allows more insight into both conserved and eukaryotic specific subunit bridges. Furthermore, the central protuberance shows signs of mobility, which is less evident in prokaryotic structure. These structures lead the way for further eukaryotic structures to reveal mechanisms behind eukaryotic-specific events such as initiation and to exploit differences from the prokaryotic ribosome for rational antibiotic design.

Perspective

In the past 10 years, there has been a veritable boom in high-resolution structural information on the ribosome. The structures highlighted here, combined with vast amounts of critical biochemical, biophysical single particle, and mutagenesis work as well as important cryo-EM results, have fantastically improved our understanding of translation. As always, there are more questions to be answered, including those related to initiation and translocation complexes and the differences between prokaryotic and eukaryotic protein synthesis. Even so, it is amazing how much our knowledge of the ribosome continues to increase.

Riboswitches

A R Ferré-D'Amaré, National Heart, Lung, and Blood Institute, National Institutes of Health, Bethesda, MD, USA

Published by Elsevier Inc.

Glossary

Aptamer Nucleic acid (DNA or RNA) molecule evolved artificially to bind to another molecule (nucleic acid, protein, or small molecule) with high affinity and specificity.

Kinetic control Said of a chemical or biochemical phenomenon whose outcome results from the relative rates of competing processes that underlie it (cf. thermodynamic control).

Pseudoknot A nucleic acid structure that results from nucleotides in the loop of a stem-loop structure forming

Watson–Crick base pairs with nucleotides outside of the stem-loop.

Riboswitch A domain of a messenger RNA (mRNA) that binds to a cellular small molecule with high specificity and regulates expression of the mRNA it is part of.

Ribozyme A catalytic RNA molecule.

Thermodynamic control Said of a chemical or biochemical phenomenon whose outcome results from the relative stabilities of the end results of competing processes that underlie it (cf. kinetic control).

Discovery

Genetic Regulation by Metabolite-Binding RNAs

In 1961, François Jacob and Jacques Monod suggested that the expression of genes that encode proteins could be regulated by a macromolecule that senses the intracellular concentration of a small-molecule metabolite. They proposed the name 'repressor' for this regulatory molecule, which would exert its function by binding to a specific nucleic acid sequence called the 'operator'. Although, at that time, Jacob and Monod speculated that the repressor could be either a protein or RNA, it was eventually shown that the particular repressor these researchers were investigating (the *lac* repressor) is a protein that binds to its cognate DNA sequence in the absence of allolactose. Nonetheless, this early postulation of an RNA genetic regulator that directly binds to small molecules presaged the discovery of riboswitches.

Antecedents

Several developments set the stage for the discovery of riboswitches. First, the invention of the systematic evolution of ligands by exponential enrichment (SELEX) methodology for the *in vitro* evolution of RNA led to the discovery of artificial RNAs (named 'aptamers') that are capable of binding other molecules with high affinity and specificity. Aptamers have been selected that recognize a variety of ligands, ranging from simple metabolites such as amino acids and nucleobases to complex secondary metabolites and even proteins. These aptamer selection experiments demonstrated that RNA has the capability of folding into structures that can recognize ligands with exquisite selectivity. Moreover, the results of these experiments also imply that such RNA sequences are relatively common in sequence space, because typical *in vitro* selection experiments can only sample a minuscule portion of the total number of possible RNA sequences of a given length (for instance, $\sim 10^{14}$ out of a total of $\sim 10^{60}$ possible sequences for a 100 nucleotide RNA). Second, a variety of mechanisms

for the control of gene expression that take place in *cis* at the messenger RNA (mRNA) level were discovered. Examples of these include transcriptional attenuation, where the efficiency of mRNA production is modulated by an mRNA-binding protein that is sensitive to the intracellular concentration of a metabolite, and translational attenuation, in which the efficiency of ribosome binding to an mRNA is controlled by a small-molecule-binding protein that binds to a regulatory domain of the mRNA. Third, an example of genetic regulation by attenuation that does not rely on a protein sensor was discovered. It was found that the 5'-untranslated region (UTR) of mRNAs encoding aminoacyl-tRNA synthetases (ARSs) in a number of Gram-positive bacteria can directly bind to the cognate transfer RNA (tRNA) of the ARSs they encode. These UTRs, characterized by a sequence and structural motif called the 'T box,' recognize both, the identity of the tRNA (through base pairing with the anti-codon sequence of the tRNA) and whether or not the tRNA is charged (aminoacylated). The T-box element functions as a genetic switch, promoting production of the ARS encoded in the mRNA of which they are part, when the concentration of uncharged cognate tRNA rises, and suppressing production of the ARS when aminoacylated tRNA becomes abundant.

Defining Characteristics of Riboswitches

Riboswitches were discovered in the first years of the twenty-first century, and embody aspects of RNA function that first became apparent from the three lines of research summarized above. First, riboswitches are RNA domains that bind to small molecule metabolites with high affinity and specificity. Although no natural riboswitch has been discovered to date that employs the same three-dimensional structure to bind to a small molecule as that used by an *in vitro*-evolved RNA, the affinity and selectivity of riboswitches for their cognate small molecules rival, and typically surpass, those of man-made aptamers that bind to the same ligands. Second, riboswitches function in *cis* at the mRNA level. These are domains of mRNAs

that modulate the expression of the mRNAs of which they are part. In this, they differ from the repressor of Jacob and Monod, since this latter type of gene regulation occurs in *trans* (i.e., regulation is effected by a molecule that is not covalently part of the mRNA), but riboswitch function is analogous to those of mRNAs regulated by attenuation. Third, like the T box, riboswitches are mRNA domains that can sense the intracellular concentration of a molecule directly, without employing a protein. Unlike the T box, which recognizes a macromolecule (tRNA), riboswitches respond to the concentration of small-molecule metabolites. This is an arbitrary distinction.

Heuristics and Their Consequences

All known riboswitches have sequence (and structural) elements that are highly conserved between multiple species. Some riboswitches are encoded in more than one genomic locus in an organism (i.e., they control multiple distinct mRNAs encoded by different genes or operons), and in such instances, a high level of conservation is also present within a species. Indeed, the majority of known riboswitches has been discovered by computational alignment of the sequences of noncoding mRNA elements (such as UTRs or introns). In some instances, previous genetic and biochemical experiments had already indicated that the aligned UTRs were responsible for regulation of the expression of the mRNA in response to the concentration of a particular metabolite. In other cases, the ability of the conserved mRNA element to regulate gene expression is unknown and has to be determined after discovery of the element. In either case, the identity of the physiologic ligand needs to be established experimentally and often involves educated guesses based on the nature of the proteins encoded by the mRNAs of which the putative riboswitch is part. These heuristics may have biased the types of riboswitches discovered to date, in that most known riboswitches are bacterial, and regulate the metabolism or transport of primary metabolites. Discovery of highly conserved noncoding mRNA elements is easier in bacteria, in which UTRs are rarely longer than a few hundred nucleotides. By contrast, UTRs and introns can be much longer in eukaryotic mRNAs. The number of sequenced bacterial genomes is also much larger than those of eukaryotes. In addition, the mRNAs of proteins involved in central metabolic pathways are much better annotated than those of proteins involved in other aspects of cellular function. Thus, the nature of the potential ligands for a newly discovered conserved UTR is more easily established for mRNAs encoding proteins that participate in primary metabolism. Finally, the reliance on sequence conservation as a heuristic necessarily excludes the discovery of riboswitches that are present in a single or only a few species.

Riboswitch Structures and Classes

Domain Structure

Riboswitches are not freestanding molecules; rather, they are functional domains embedded within mRNAs. Therefore, the first step in classifying them is to define their domain

borders. Biochemical analyses indicate that the borders of functional riboswitches extend beyond the segments with high phylogenetic conservation. Specifically, while the segments with high sequence conservation are often sufficient for recognition of the cognate small molecule, genetic regulation requires segments that are typically 3' of the conserved core. By analogy to *in vitro* selected RNAs, the conserved core is referred to as the 'aptamer domain'. Many riboswitch aptamer domains have been found to be autonomously folding and functional units, that is, these are RNA domains in the structural sense. The less conserved segments that are needed for regulation of gene expression are thought to transduce the small molecule-binding event to the gene expression machinery. These segments are collectively known as the 'expression platform'.

Riboswitch Ligands

Riboswitches can be classified based on their cognate ligands. The ligands of currently known riboswitches fall into five classes. First, riboswitches that respond to a variety of coenzymes and enzyme cofactors, including thiamine pyrophosphate (TPP), flavin mononucleotide (FMN), adenosylcobalamin, S-adenosylmethionine (SAM), and the molybdenum and tungsten cofactors Moco and Tuco, are known. Second, several riboswitches recognize purines and purine nucleosides, including adenine, guanine, preQ₁ (7-deaza-7-aminomethylguanine), and 2'-deoxyguanosine. A riboswitch that binds the bacterial second messenger cyclic diguanylate has also been discovered. Third, riboswitches that recognize amino acids include the glycine and lysine riboswitches. Fourth, one riboswitch that recognizes a carbohydrate, glucosamine-6-phosphate (GlcN6P), has been described. Fifth, riboswitches sensitive to the intracellular concentration of divalent cations have been described.

Aptamer Domain Structures

Classification of riboswitches based on their cognate ligands is unsatisfactory because several ligands are recognized by more than one type of riboswitch. For instance, five different types of riboswitches have been described that recognize SAM. Crystal structures have been determined of the aptamer domains of SAM riboswitches belonging to three of the five different types, and these demonstrated that not only are the folds of the RNAs different, but the interactions that the three types of RNAs employ to recognize SAM are distinctly different. Is a structural classification of riboswitches more meaningful? As of this writing, crystal structures of the ligand-bound conformations of a dozen riboswitch aptamer domains have been determined. Except for those riboswitches that are members of the same family (i.e., TPP riboswitches from *Escherichia coli* and *Arabidopsis thaliana*, or the adenine and guanine riboswitches, which are very closely related in sequence and nearly identical in structure), the structures of different riboswitches do not suggest evolutionary relationships between them, and therefore do not form a basis for a natural classification.

Crystal structures do allow classification of riboswitches based on RNA architectural principles. For instance, riboswitch

aptamer domains can be broadly divided into those that are assembled around a multi-helical junction and those that employ pseudoknotting. An example of the former is the FMN riboswitch, which is comprised of six stem loops radiating from a central junction. Five of the stem loops fold back on each other making a series of complex loop–helix and loop–loop interactions that give rise to the folded structure, which is pseudo-two-fold symmetric. A single FMN molecule is bound asymmetrically as a magnesium ion chelate at the core of the RNA (Figure 1(a)). Pseudoknots are nucleic acid structures that form when nucleotides in the loop of a stem–loop base pair with nucleotides outside of the stem–loop. This has the result of producing two helices that are connected by three nonhelical segments (at least formally, since some of these connectors can be as short as a single phosphodiester bond, i.e., be of length zero). The SAM-II (the second of the SAM riboswitch types to be described) is an example of a riboswitch that is a compact pseudoknot, in which the two constituent helices stack coaxially. The SAM molecule is recognized at a discontinuity internal to one of the two helices (Figure 1(b)). The *glmS* riboswitch recognizes GlcN6P and is an example of an RNA comprised of several pseudoknots. This RNA consists of a core domain that is sufficient for GlcN6P binding and a peripheral domain that stabilizes the core (Figure 1(c)). The core domain is made up of three helices that are connected by four crossovers, forming a double pseudoknot. The peripheral domain is connected to the core by an additional pseudoknot (resembling the SAM-II riboswitch). One of the loops of this peripheral domain is a long stem loop, so that the peripheral pseudoknot in effect functions as a helical junction. These three RNAs are but examples of the

diversity of structural solutions that nature has evolved to function as riboswitches.

Riboswitch Function

Small Molecule Recognition

The details of the molecular interactions employed by riboswitches to recognize their cognate small molecules are highly idiosyncratic. Nonetheless, the intrinsic chemical properties of RNA are reflected in two recurrent recognition strategies. First, planar heterocycles tend to be recognized in the same manner in which purine and pyrimidine nucleobases of an RNA pack in the interior of a molecule, that is, through a combination of stacking interactions and hydrogen bonding. This is most obvious in the case of riboswitches that bind to purines and purine nucleosides and nucleotides, and ligands such as SAM that contain a nucleotide moiety, but it extends to other ligands with different heterocycles. For instance, the thiamine moiety of TPP consists of a thiazole and an aminopyrimidine. The latter is recognized by the TPP riboswitch by making an interaction analogous to a sugar-edge base pair with a guanosine residue of the riboswitch, and by stacking it between two RNA nucleobases. The FMN riboswitch also recognizes its ligand in a base pair-like manner. In this case, one of the edges of the isoalloxazine ring of FMN makes an interaction analogous to a Watson–Crick base pair with an adenosine residue of the ribozyme. Second, negatively charged ligands are often recognized as cation chelates. A magnesium ion coordinates the phosphate of FMN bound to the riboswitch, and two magnesium ions chelate the pyrophosphate moiety of TPP bound to its cognate riboswitch. In both cases, the metal ions are partially solvated, and the inner-sphere-coordinated water molecules mediate many of the RNA–metal ion interactions. That is, the riboswitch recognizes neither the naked ligand nor the metal ion chelate, but the hydrated metal ion chelate. Another example of cation-mediated recognition is the lysine riboswitch, which employs a potassium ion to mediate interactions between the RNA and the carboxylate functional group of its ligand.

The importance of some of the riboswitch–small molecule interactions revealed by X-ray crystallography has been addressed experimentally. The adenine and guanine riboswitches are closely related structurally, and both recognize their ligands by completely enveloping them. Almost all the hydrogen-bonding groups of the bound purines are recognized by riboswitch functional groups. Mutagenesis experiments indicate that the specificity of the adenine and guanine riboswitches is controlled by a single pyrimidine residue at a position in the RNAs that makes a Watson–Crick-type interaction with the bound ligand. Thus, if the riboswitch contains a cytidine residue at this position, it will bind to guanine, and if the riboswitch contains a uridine at the same position, it will be specific for adenine. In other riboswitches, the specificity is not such a simple function of RNA sequence.

The importance of metal ion ligands for ligand recognition varies from riboswitch to riboswitch. The lysine riboswitch has a strong preference for potassium, since replacing this cation with sodium or magnesium ions reduces the affinity of the RNA for its ligand by 50- to 100-fold. *In vitro*, the TPP riboswitch will bind to its ligand when Mg^{2+} is replaced with

Mn^{2+} , or even Ca^{2+} or Ba^{2+} . Structure analysis of this RNA bound to thiamine monophosphate (TMP) demonstrated a striking degree of plasticity: when bound to TMP, which has one phosphate group less than the cognate ligand TPP, the riboswitch still employs two metal ions that make essentially the same contacts with the RNA as the two ions that chelate TPP. However, the RNA has to deform to bind to the smaller TMP using this strategy. Thermodynamic analysis shows that this accommodation results in considerably weaker binding of TMP ($K_d \sim 260$ nM) than TPP ($K_d \sim 8.4$ nM, both measured at 10 mM Mg^{2+} concentration).

The degree of burial of riboswitch ligands in the interior of the aptamer domain varies from case to case. The purine-responsive riboswitches almost completely envelop their ligands, whereas the c-di-GMP-responsive riboswitch buries the nucleobases of its ligand, but leaves parts of the phosphate-ribose backbone of c-di-GMP exposed to solvent. The TPP riboswitch buries the pyrophosphate and aminopyrimidine moieties at either end of its ligand, but makes very few interactions with the thiazole ring in the center of TPP. The affinity of riboswitches for their ligands is highly variable and presumably reflects the intracellular concentration range over which the riboswitch has to carry out its genetic control function. Regardless of the precise affinity, however, it appears that binding of riboswitches to their ligands is in general accompanied by folding of the RNA, at least at the local level. Thus, studies of riboswitch–ligand interactions by isothermal titration calorimetry show that binding is enthalpically driven. Since RNA folding is facilitated by divalent cations, analysis of binding experiments at higher concentrations of Mg^{2+} shows a reduction in the unfavorable entropy of binding. That is, preorganization of riboswitch aptamer domains facilitates ligand recognition. A particularly interesting elaboration of the mechanism of ligand binding is present in the glycine riboswitch. This regulatory RNA is comprised of two aptamer domains that can recognize glycine independently. However, in the full riboswitch, the two domains interact, resulting in positive cooperativity in glycine binding, with a Hill coefficient of ~ 1.6 .

Gene Regulation: an Example

The mechanisms by which ligand binding to a riboswitch results in alterations in gene expression, that is, the mode of action of the riboswitch expression platforms, are highly variable, but with the exception of the *glmS* riboswitch discussed separately below, most appear to function by adopting two mutually exclusive secondary structures as a result of ligand binding. The alternative structures adopted by the expression platform of the TPP riboswitch upstream of the *ThiM* gene in *E. coli*, which functions by translational attenuation, illustrate this (Figure 2). The aptamer domain lies upstream of the open reading frame (ORF), and it is transcribed first. As RNA polymerase transcribes the end of the aptamer domain, a decision is made based on the presence of sufficiently high concentrations of TPP. In the presence of TPP, the aptamer domain structure is stabilized, and this results in formation of a helix (or paired region) P1, between the initial and final segments of the aptamer domain. Stabilization of this helix P1 allows the subsequent transcript to fold into a long helix comprised of three coaxially stacked helices (P6, P7, and P8). Helix P8 is

formed by nucleotides that comprise the Shine–Delgarno element (required for ribosome binding and initiation of translation) and a complementary anti-Shine–Delgarno sequence. When the expression platform (which, in this case, includes sequences starting at the 3' side of P1 to the end of P6) is in this conformation, the mRNA is not translated. In the absence of sufficient TPP, the aptamer domain is not stabilized, and the nucleotides that form the 3' side of P1 in the TPP-bound form instead form a new helix (PX in Figure 2) by pairing with the anti-Shine–Delgarno nucleotides. This results in exposure of the Shine–Delgarno sequence, and translation of the mRNA.

Transcriptional and Translational Control

It is apparent from the example in Figure 2 that similar alternative folding strategies could be devised where the riboswitch allows translation to take place in the absence of cognate ligand, and indeed such examples of translation-on riboswitches exist in nature. Many bacterial riboswitches function as transcriptional switches. In those cases, the mutually exclusive secondary structures include a transcriptional terminator helix and a helix that sequesters one of the strands of the terminator (an anti-terminator helix). As in the case of riboswitches that function by translation attenuation, transcriptional riboswitches are also known that activate or repress transcription depending on ligand occupancy. Indeed, the TPP riboswitch has been found to function by all four mechanisms in bacteria, depending on its genetic context. The different examples of TPP riboswitch all share a highly conserved aptamer domain, but differ in their expression platforms.

Riboswitches and Alternative Splicing

Thus far, the TPP riboswitch is the only riboswitch discovered in eukaryotes. It has been found in introns of several genes that appear to encode proteins linked to TPP metabolism or transport in filamentous fungi, algae, and plants. In all cases examined, TPP riboswitches in eukaryotes appear to function by promoting alternative splicing as a function of TPP concentration. The specific consequences of alternative splicing vary from example to example. In some fungal genes, the TPP riboswitch is present in the first intron, and depending on whether this intron is spliced or not, the mRNA will encode small upstream open reading frames (uORFs) whose translation downregulates translation of the principal ORF encoded by the mRNA. In the case of some mRNAs from *A. thaliana*, the TPP riboswitch is present in the last intron of the pre-mRNA. When the intron is not spliced, a strong polyadenylation signal will be present close to the end of the ORF. When the intron is spliced, a weaker polyadenylation signal much further downstream of the ORF is employed. This weaker signal results in a less stable mRNA, possibly because of a process involving nonsense-mediated decay (NMD).

Kinetic versus Thermodynamic Control

Since riboswitches make gene control decisions at the mRNA level, it is possible, in principle, that they can function either by thermodynamic or by kinetic control. A riboswitch would be

Figure 2 Schematic of the mechanism of translational control by two states of the TPP riboswitch from the *ThiM* gene of *E. coli*. Left, transcription of the mRNA generates the aptamer domain. In the presence of sufficient TPP (bottom) the aptamer domain is stabilized, and a helix that sequesters the Shine-Dalgarno sequence is formed. This results in downregulation of translation. In the absence of sufficient TPP to bind to the aptamer domain (top), the aptamer domain is not stable and the switch segment (orange) base pairs with the anti-Shine-Dalgarno sequence. This exposes the Shine-Dalgarno sequence allowing translation of the downstream ORF to take place.

under thermodynamic control if ligand binding and release are fast compared to the rate of mRNA synthesis, and therefore the ligand-bound and free forms of the riboswitch equilibrate quickly. Conversely, if the rate of mRNA synthesis is comparable to or faster than the rate of ligand binding, the switch decision occurs co-transcriptionally. Moreover, concentrations of ligand much higher than the equilibrium dissociation constant may be needed to throw the switch. Studies of the kinetics and thermodynamics of ligand binding by the FMN riboswitch demonstrated that the rate of ligand binding by the RNA is slow compared to the rate of transcription, such that unless the RNA polymerase is slowed down by encountering strategically positioned pause sites, the riboswitch cannot fold and bind FMN in time for its expression platform to adopt a secondary structure that is consistent with the liganded state of the aptamer domain.

Conformational Switching

Is ligand binding accompanied by a global folding transition of riboswitch aptamer domains, and not just a change in structure of the expression platform? That is, do ligand-free riboswitch aptamer domains adopt defined conformations, or are they partially or completely unfolded? Most structural studies of riboswitch aptamer domains have concentrated on their ligand-bound states. Recently, a number of studies of the ligand-free states of riboswitch aptamer domain have been reported. For instance, the TPP riboswitch has been examined by small-angle X-ray scattering (SAXS). In addition to providing global measurements of molecular size, SAXS can be used to generate low-resolution molecular envelopes. The molecular envelope of the ligand-bound state of the TPP riboswitch closely approximates the Y-shaped crystal structure of the

Figure 3 Conformational switch of the TPP riboswitch aptamer domain in solution. (a) Ribbon and stick representation of the crystal structure of the aptamer domain from the *ThiM* TPP riboswitch. (b) Low-resolution molecular envelope generated from SAXS data collected on the TPP-bound aptamer domain in solution. Portions of the reconstruction are colored to match the secondary structure elements in panel (a). (c) SAXS molecular envelope of the ligand-free state of the TPP riboswitch. The helix colored blue in panel (a) appears to have swung away from the red helix.

same state (Figures 3(a) and 3(b)). By contrast, the ligand-free state (which appears to be dominated by a single conformation, rather than a complex of states) is much more elongated than the crystal structure (Figure 3(c)). Thus, the TPP riboswitch aptamer domain exhibits distinct bound and free conformations. Other aptamer domains, such as those of the FMN and lysine riboswitches, appear to be pre-formed and do not exhibit global conformational changes concomitant with ligand binding.

The Special Case of the *GlmS* Riboswitch

The *glmS* riboswitch from Gram-positive bacteria functions by a mechanism that is thus far unique. This riboswitch resides in the 5'-UTR of the mRNA encoding the enzyme GlcN6P synthetase (*GlmS*). Binding of GlcN6P (its cognate ligand) to the riboswitch uncovers a latent self-cleavage activity of the RNA. In Gram-positive bacteria, intact mRNAs are capped by a 5' triphosphate. Activation of the *glmS* ribozyme by high levels of GlcN6P releases a short leader sequence that bears the triphosphate and exposes a new 5'-OH group in the ribozyme domain. This hydroxyl group is recognized by RNase J1, a ribonuclease that degrades the mRNA. Because the *GlmS* protein is unstable, degradation of the its mRNA results in downregulation of the enzymatic activity, thus completing a negative-feedback loop. The physiologic importance of the *glmS* ribozyme has been demonstrated by employing ribozyme-riboswitch mutants that lack GlcN6P-induced self-cleavage activity. *Bacillus subtilis* strains harboring *glmS* genes downstream of such catalytically defective riboswitches fail to sporulate under conditions that lead to sporulation of wild-type bacteria. Presumably, the differentiation program leading to sporulation requires precise regulation of GlcN6P levels.

Riboswitches as Drug Targets

Riboswitches are potential targets for the development of new antibacterial compounds for three principal reasons. First, the

currently known riboswitches are primarily bacterial. Thus, if riboswitches can be targeted specifically, the potential for undesired off-target interactions with human molecules is lessened. Second, riboswitches have evolved to bind small molecules with high affinity and specificity. Thus, they demonstrate that RNA (or at least some RNAs) can achieve highly specific binding. Third, riboswitches regulate essential metabolic pathways. One riboswitch is known that binds to a bacteria-specific second messenger. Thus, alteration of riboswitch function may significantly reduce the fitness of a bacterial pathogen. Indeed, several compounds whose anti-bacterial activity had been identified before the discovery of riboswitches have been shown subsequently to function by binding to riboswitches, and mutations in those riboswitches have been shown to diminish the effectiveness of these compounds.

Glossary

Abiotic Formed in the absence of life.

Nucleotide A chemical subunit of nucleic acids (A, adenosine; C, cytidine; G, guanosine; U, uridine).

Phylogeny A tree-like representation of the ancestral-descendant relationships among species.

Polypeptide A polymer of amino acids that forms a protein.

Ribozyme An enzyme made of RNA.

RNA Ribonucleic acid, a polymer of nucleotide subunits.

Ribozymes, also known as ribonucleic acid (RNA) enzymes, have been known since the early 1980s when it was first discovered that RNA could catalyze chemical reactions. Previously, it had been thought that all enzymes were proteins, but it is now clear that RNA-directed catalysis plays many important cellular functions, and that numerous ribozymes can be found in organisms spanning the tree of life. Notably, for example, we now realize that the catalytic core of the ribosome itself, the cellular machinery for protein synthesis, consists of RNA such that peptide-bond formation is catalyzed by ribosomal RNA. These findings strongly suggest that RNA, or some RNA-like molecule, was an integral piece of the earliest biochemical processes to evolve on the Earth. In 1986, Gilbert coined the phrase 'RNA World' to invoke a time during the coalescence of life when RNA was responsible for most, if not all, of the genetic transformations of the planet's first organisms. Ribozymes have, thus, played an important role in biological evolution and have recently been used to perform evolution experiments in the laboratory.

Ribonucleic Acid

RNA is a polymer of ribonucleotides. RNA differs from DNA in three basic respects. First, RNA employs uracil as a nitrogenous base, in place of the thymine used in DNA. Second, RNA nucleotides possess a hydroxyl group at the 2' position, while DNA is deoxygenated at that position to a proton. Third, RNA is more often found single stranded than DNA, which is typically completely base paired into a double helix. All three of these features help engender RNA with catalytic capabilities, although they also tend to make RNA chains less chemically stable than DNA. From an informational point of view, both DNA and RNA have the capability to store and transmit biological information through complementary base pairing: C with G and T(U) with A.

Catalytic RNA

RNA as an Enzyme

Enzymes are molecules that can catalyze a chemical reaction by lowering the activation energy needed to transit from reactants

to products. Proteins, built up from amino acids of 20 or more varieties, are well known to perform catalysis in biological systems. RNA is built up from only four nucleotide varieties but still can perform catalysis. Similar to protein-directed catalysis, the basis for this is the acquisition of a three-dimensional structure that contains a catalytic pocket. Many ribozymes can speed up the rate of reaction 10^3 – 10^{11} -fold over the corresponding uncatalyzed rate and, in certain cases, can behave as true enzymes by 'turning over', catalyzing more than one reaction event.

Chemistry

In the catalytic pocket, RNA usually relies on metal-ion coordination and one or more chemical strategies to accomplish catalysis. In some cases, the 2'-hydroxy group itself can serve as a nucleophile to attack a chemical bond in the substrate molecule. In other cases, the chemical moieties on the nitrogenous bases (adenine, guanine, uracil, or cytosine) can act as acids or bases to stimulate a reaction. For example, it is now thought that peptide-bond formation in the heart of the ribosome is promoted by some type of interaction between amino acids and a phylogenetically invariant adenosine residue in the ribosomal RNA. In most cases, RNA must bind divalent metals such as magnesium to help properly position the substrate molecules in order to stabilize the transition state.

Classes of Natural Ribozymes

Since 1982, nine distinct types of naturally occurring ribozymes have been discovered (Figure 1). With the notable exception of the ribosome, these ribozymes are generally limited in their capacity to making and/or breaking phosphoester bonds that hold nucleic acids together. In addition to the list below, RNA plays an important role in the catalytic events promoted by ribonucleoproteins such as telomerases, spliceosomes, and editosomes. Other natural ribozyme will undoubtedly be discovered in the near future.

- 1 and 2. *Group I and Group II Introns*. These are large (>200 nucleotides) self-splicing introns: ribosomal RNA (rRNA) or transfer RNA (tRNA) introns that excise themselves from nascent RNA transcripts via ribozyme activity.

Figure 1 Some known ribozymes. (a) The group I intron from the ciliate *Tetrahymena thermophila*. Shown is the shortened version of the natural rRNA intron; this 414-nucleotide ribozyme binds a complementary RNA substrate (lowercase letters) via complementary base pairing and catalyzes phosphoester-bond cleavage and ligation reactions at the site indicated by the arrow. (b) One possible hammerhead ribozyme. This ribozyme self-cleaves at the site indicated by the arrow.

3. *RNase P*. RNase P is a large ribozyme that allows maturation of nascent tRNA transcripts and a few other small RNAs by removing the 5'-leader portion of those transcripts.
4. *Hammerhead ribozymes*. These small ribozymes, of which there are many throughout nature, possess three base-paired stems and catalyze self-cleavage of a RNA phosphodiester bond.
5. *Hairpin ribozymes*. Like the hammerheads, hairpin ribozymes, originally found in a tobacco RNA virus, self-cleave an RNA bond, but unlike the hammerheads, consist of four stems in two general domains.
6. *Hepatitis delta virus ribozyme*. The hepatitis delta virus (HDV) ribozyme is another viral-derived small ribozyme that catalyzes RNA bond cleavage, but it is slightly more complex, having a 'pseudoknot'-folded structure.
7. *VS ribozyme*. The VS motif is another small self-cleaving ribozyme, found first in a satellite plasmid of *Neurospora* mitochondria. This ribozyme, as is the case for all RNA enzymes, can also catalyze the reverse reaction, which here would be ligation of two RNA strands.
8. *Riboswitch ribozyme*. The *glmS* gene from Gram-positive bacteria produces upon transcription an RNA that can fold into two conformations depending on the presence or absence of a small metabolite molecule, glucosamine-6-phosphate. In one of these two conformations, the RNA cleaves itself, thereby halting translation of the RNA into a protein.
9. *The ribosome*. It is now understood that the RNA portion of ribosomes contains the catalytic function of the peptidyl-transferase center, which joins two amino acids together during the translation of messenger RNA into proteins.

Unnatural Ribozymes

Using the techniques of systematic evolution of ligands by exponential enrichment (SELEX), *in vitro* selection, and *in vitro* evolution (see below), many novel catalytic RNA sequences have been discovered (Figure 2), many of which promote chemistries not yet seen in natural ribozymes. The existence of these ribozymes demonstrates not only that RNA has a wide repertoire of catalytic capabilities, but that evolutionary forces are quite adept at molding RNA-based catalysis.

1. *Ligase ribozymes*. Isolated from random pools of RNA sequences, the ligase ribozymes were the first type of unnatural ribozymes to be fashioned. These RNAs catalyze phosphoester-bond formation between themselves and an exogenous oligoribonucleotide. Several classes of ligase ribozymes exist, with differing RNA folds. Ligases catalyze bond formation by a chemistry that is distinct from that of known natural ribozymes, but which is remarkably similar to the chemistry used by the protein enzyme RNA polymerase. In fact, some ligases can be engineered to behave as rudimentary RNA polymerases.
2. *Diels-Alderase ribozymes*. To move from phosphoester chemistry to carbon-carbon bond chemistry, it was necessary to derivatize one of the four bases, uridine, with a pyridyl moiety. This allowed the selection *in vitro* of a Cu^{2+} -dependent ribozyme that could catalyze a Diels-Alder cycloaddition reaction.
3. *Three- and two-base ribozymes*. Recently, ribozymes have been selected that use only three (i.e., A, G, and U)

nucleotides to perform catalysis. Also, if only U and 2,6-diaminopurine are available, a 2-base ligase ribozyme can be constructed through *in vitro* evolution.

4. *Other unnatural ribozymes*. Many other unnatural ribozymes exist and more are being constructed. These ribozymes can catalyze amide bond formation, N-alkylation, porphyrin metallation, thioester bond formation, and a host of other chemical reactions. Catalytic centers of these ribozymes can be as small as five nucleotides.

Phylogenetic Distribution of Ribozymes

Judging from the phylogenetic distribution of natural ribozymes (Figure 3) and from the central nature of the reactions that they catalyze, it is clear that catalytic RNA was likely present in the last common universal ancestor (LUCA) of contemporary life. Group I ribozymes, for example, are present in eukaryotes (e.g., the ciliated protozoan *Tetrahymena*) and in eubacteria, including some bacteria thought to occupy basal lineages in the tree of life (e.g., the hyperthermophilic bacterium *Thermotoga*). Ribozymes are wide spread in RNA viruses, group II introns have been isolated from deep-sea hydrothermal vent bacteria, and small ribozymes have been isolated from genomes in organelles such as mitochondria and chloroplasts. Also, the RNase P ribozyme is present in a variety of archaeal species.

RNA and the Origins of Life

In addition to the inference that ribozymes were a feature in the LUCA, there is much evidence and corresponding speculation that RNA, in particular catalytic RNA, was critical in the earliest life forms on the Earth. RNA, or an RNA-like molecule, could even have been the basis for the origins of life itself. Initially, this postulate was based on the observation that RNA was the only known polymer to possess simultaneously a genotype and a phenotype. Subsequently, more direct evidence of the antiquity of RNA has come to light. These data include the realization that the ribosome is a ribozyme, that RNA can catalyze a diverse array of reactions, a ligase-derived RNA can catalyze rudimentary RNA polymerization, RNA can catalyze recombination, and, importantly, that populations of RNA can evolve in a test tube and respond to environmental pressures in manners quite analogous to natural populations of organisms. Moreover, much is now known about plausible abiotic synthetic routes to RNA precursors such as purines, pyrimidines, carbohydrates, and phosphorylated compounds. For example, cationic clays such as montmorillonite can promote the polymerization of RNA-like monomers into RNA chains of 50 or more nucleotides in length.

In Vitro Evolution of RNA

Systematic Evolution of Ligands by Exponential Enrichment

SELEX is a powerful method to isolate RNA sequences that bind to particular substrates without necessarily reacting with them. Random pools of RNA, typically 40–100 nucleotides in

Figure 3 Distribution of ribozymes in the tree of life. The examples shown here are not exhaustive; branch lengths are not indicative of extinction events or amount of evolutionary change. Mitochondria (mt) and chloroplasts (cp) are included with their bacterial precursors. HDV-like ribozymes have been detected in the human genome.

the initial pool can either be a set of random RNA sequences, or a set of mutants based on a particular known wild-type sequence.

Evolution *In Vitro*

Evolution *in vitro* follows the strategy of selection *in vitro* except that in each round, mutations are deliberately introduced into the RNA population to provide additional variation on which natural selection can operate (Figure 4). The mutation can come from error-prone protein polymerase enzymes, from mutagenic polymerase chain reaction (PCR) or from sexual PCR. Evolution *in vitro* can in principle be carried out for an indefinite number of rounds, but in principle convergence on a particular catalytic solution, if one exists, typically occurs after 10–20 rounds and will occur in general accordance to the principles of population genetics.

Continuous Evolution *In Vitro*

The most recent modification of these RNA evolution techniques is to mimic a prebiological milieu in which all the components of evolution – the RNA, the nucleotides, the salts, the oligonucleotides, and the protein enzymes, if any – are simultaneously present in a single test tube. In this fashion, several rounds of evolution occur autonomously before equilibrium is reached. Serial dilution and fresh additions of

Figure 4 *In vitro* selection/evolution. A pool of RNA molecules, partially or completely randomized in nucleotide sequence, are challenged to perform a novel binding and/or catalytic event. As a result of successfully performing that event, RNA molecules become physically tagged in such a manner that they can be separated from unsuccessful RNA molecules. The successful RNAs then get converted to a corresponding DNA sequence through reverse transcription and back into RNA by forward transcription. A complete cycle is called a round, or a generation, and may or may not include mutagenic steps (indicated by asterisks) to introduce an evolutionary element into the process.

reagents can result in the extremely rapid evolution of RNA populations.

Glossary

Helicases Enzymes that move directionally along DNA or RNA duplexes, thereby separating (unwinding) the two nucleic acid strands in an ATP-dependent manner.

Intron A noncoding RNA region that interrupts a protein-coding mRNA sequence or intervenes non-protein-coding RNA sequences. Accordingly, an intron has to be removed from the precursor RNA by a process named splicing.

RNA folding The process that describes how an RNA undergoes the structural transition from the

unfolded disordered state to the native, functional conformation.

Self-splicing introns (group I and group II introns)

Catalyze their own excision from the precursor RNA through two sequential transesterification reactions.

Spliceosome A large complex that consists of small nuclear ribonucleoproteins (snRNPs) and facilitates splicing of most eukaryotic introns, so-called nuclear introns, which are not capable of self-splicing.

Splicing The process by which introns are excised out of the primary RNA transcript and exons (i.e., coding regions) are joined together to generate the mature RNA.

Introduction

Group II introns are large, multidomain RNAs that are capable of self-splicing. This abundant class of catalytic RNA is found in bacteria, lower eukaryotes and in organelles of higher eukaryotes. Although these introns do not share a lot of sequence conservation, their secondary structure organization is highly conserved, consisting of six major domains (DI–DVI), which radiate from a central wheel (**Figure 1**). Notably, group II introns can be subdivided into three main phylogenetic families, the IIA, IIB, and IIC introns, and two minor groups, the IID and IIE introns. Like most RNAs, group II introns have to adopt a specific 3D architecture to be functional. Numerous tertiary contacts are required to assemble the individual intron domains into the catalytically active conformation. *In vitro* high-salt and elevated temperature are typically necessary to promote self-splicing of group II introns. By contrast, in the cell these introns depend on protein cofactors, such as intron-encoded maturases or host-encoded splicing factors, to promote their own excision from the precursor RNA. A hallmark of this intron class is their catalytic versatility, with forward splicing, reverse splicing, and trans-splicing being the most notable examples. In the first step of splicing, the 2′OH group of a bulged adenosine in DVI, the so-called branch point, acts as a nucleophile to attack the 5′-splice site, resulting in the release of the upstream exon and in a covalent bond (2′–5′ linkage) between the 5′ end of the intron and the branch-point adenosine (**Figure 2(a)**). In the second step, the 3′OH group of the liberated 5′ exon attacks the 3′-splice site, resulting in exon ligation and the intron is released as lariat. Alternatively, to this branching pathway, a water molecule can act as a nucleophile in the first transesterification, which eventually results in ligated exons, but the intron is excised in a linear form (**Figure 2(b)**). Notably, in the case of the yeast mitochondrial intron ai5γ, the branching pathway is the predominant splicing mechanism in the cell, but the hydrolytic pathway does exist *in vivo* as well. However, there are group II introns

that, unlike ai5γ, do not possess a branch point, implying that these variants splice predominantly through hydrolysis. Importantly, the excised intron remains active and is able to catalyze reverse splicing into RNA and DNA substrates (**Figure 2(c)**), which represents the first step toward intron homing. This process, however, strictly depends on intron-specific maturases, which comprise RNA-binding, DNA endonuclease and reverse transcriptase motifs, and form an RNP complex with their intron. This astounding ability makes group II introns mobile genetic elements, which contribute to the genomic organization of their hosts. Another essential feature of these introns is their striking modularity. This characteristic had been used *in vitro* to create diverse group II intron-derived ribozymes of different size, catalytic proficiency, and domain content. Notably, individual domains can be efficiently assembled *in trans*. This striking phenomenon is also found in plant organelles, where two- or tri-partite introns naturally exist. These split introns form the functional structure and splice *in trans*. The modular nature of group II introns and their dominant splicing mechanism gave rise to the theory of group II introns sharing a common ancestor with the spliceosome – a large RNP machinery involved in nuclear intron splicing.

This article focuses on the structural elements and the folding mechanism of group II introns. For an in-depth discussion of group II intron evolution, their role as mobile elements and their protein collaborators, the reader is directed to recent articles on these topics by Belfort, Lambowitz, Michel, Pyle, Zimmerly, and their co-workers.

The Structural Organization of Group II Introns

Domain I

DI is the largest domain, which provides the scaffold for docking of other intron domains and the exon-binding sites (EBS1 and EBS2). Together with the catalytic center DV, which is firmly anchored in the DI scaffold through two long-range

Figure 1 The conserved secondary structure organization of group II introns. The *Sc. coxI/ai5 γ* group IIB intron is shown as an example, whereby only the basal stems of DII and DIV are shown. Long-range tertiary interaction partners are indicated with Greek symbols. The κ - ζ element, which plays an important role in ai5 γ folding, is highlighted in gray. Some group II introns contain ORFs coding for a maturase protein within DIV.

interactions (κ - κ' and ζ - ζ'), DI forms the minimal group II ribozyme. DI does not only provide the platform for active-site assembly, but also harbors essential active-site constituents, like ε - ε' and λ - λ' . The DI architecture itself is characterized by the intradomain tertiary contacts α - α' and β - β' , of which only the former is shared by all group II introns, while the latter is not strictly conserved. The five-way junction from which the main substructures of DI protrude is another key feature of the DI structural organization, as it influences the spatial arrangement of critical elements such as the EBS sites, the DV docking region, and residues engaging in tertiary interactions (α , α' , β , β' , θ , ε' , and λ). Another intriguing DI feature is that, part of its secondary structure has a high contact order (e.g., stem d and stem i). In the case of the ai5 γ intron, formation of these helical structures depends on a protein cofactor in yeast mitochondria (Liebeg, Mayer, and Waldsich), while magnesium ions are essential for their formation of stem d *in vitro*. Given its central role in the intron architecture, it was not surprising to discover that DI is an independent folding unit, which adopts the same core structure by itself as within the intron

context (except for the active-site constituents), thereby providing a preorganized scaffold for subsequent docking of other intron domains.

Domain II

DII is not strictly required for group II intron catalysis. In group II introns from different organisms, this domain exhibits substantial variability in sequence and size. However, it is somewhat conserved with respect to tertiary interactions it forms with other domains. DII is involved in two long-range tetraloop-receptor type tertiary contacts with DI (θ - θ') and DVI (η - η'). The former is believed to stabilize the tertiary fold of the ribozyme, while the latter may play a role as a conformational switch between first and second steps of splicing. Biochemical data strongly indicate that the formation of η - η' contact is detrimental for the first step of splicing, while beneficial for the second step. Disruption of the η - η' contact severely impairs the second step of splicing, while the first step is either unaffected (in IIB introns) or enhanced (in IIA

Figure 2 The splicing pathway of group II and nuclear introns. (a) The branching pathway of group II introns, in which the 2'OH of the branch-point adenosine makes the nucleophilic attack at the 5'-splice site and the intron is released in a lariat form. (b) The hydrolytic pathway of group II introns, in which water acts as a nucleophile in the first step of splicing and the intron is excised in a linear form. (c) Group II introns are capable of reverse splicing into RNA and DNA substrates. This is the first step toward intron homing, which depends on intron-encoded maturases (indicated as dark gray sphere). (d) Spliceosomal intron splicing, which is mechanistically similar to the branching pathway of group II introns (a). The light gray ellipse symbolizes the spliceosome, which catalyzes splicing of nuclear introns in eukaryotes. The upstream and downstream exons are shown as white and black boxes, respectively, while the intron is displayed as a black line.

and some IIB introns). By contrast, strengthening this contact nearly abolishes the first transesterification. These data suggest that for efficient group II intron splicing, $\eta-\eta'$ interaction must form after the first step. Another important function of DII is that its basal stem helps correctly position the joiner between DII and DIII (J2/3), which is an essential active-site element, in the catalytic core of the ribozyme.

Domain III

DIII is frequently referred to as a 'catalytic effector'. Although its presence is not absolutely necessary for the group II intron catalysis, it substantially accelerates all reactions catalyzed by the group II ribozyme. One of the most conserved elements of DIII (and the intron itself) is an A-rich internal bulge, which is essential for catalytic activity. It forms a series of noncanonical base pairs which, in group IIA and IIC introns, results in a loop E-like motif. Multiple biochemical data suggest that in IIB introns, the conserved A-rich bulge is located in close proximity to the 5'-splice site and the dinucleotide bulge of DV, which are important active-site elements. In group IIB introns, DIII structure includes a GUAAY pentaloop capping DIIIa stem. NAIS studies revealed an interaction ($\mu-\mu'$) between the two adenosines from this loop contacting the backbone of G844 (ai5 γ numbering) in DV, which is adjacent to the $\kappa-\kappa'$ contact between DV and DI. Recent crystallographic data suggest that in IIC introns DIII may adopt a slightly different orientation than that in IIB introns. However, both conformations are consistent with DIII acting as an allosteric catalytic effector, by stabilizing the active site via a complex network of interactions with other domains.

Domain IV

In some group II introns, DIV encodes an open reading frame for a maturase protein and contains a primary binding site for the maturase. This protein is intron specific, and it plays an important part in splicing, reverse-splicing, and retro-homing of the intron. In ORF-less introns, DIV has no specific function and is dispensable for catalysis.

Domain V

DV is the catalytic heart of a group II intron. It is the smallest and the most conserved domain of the ribozyme. DV is a 34-nucleotide hairpin, which contains an asymmetric dinucleotide bulge and is generally capped with a GNRA tetraloop. When DV is deleted, the catalytic activity of group II ribozymes is completely abolished. Mutational analysis, single atom substitutions and NAIM revealed multiple residues in DV that are critical for catalysis. Among these residues is the dinucleotide bulge and a so-called 'catalytic triad' AGC, which is located at positions 2–4 of the basal stem of DV. Although base identity of A and C residues of the catalytic triad is less critical than their participation in Watson–Crick base-pairing with the opposite strand, G is completely invariant. Single atom substitutions at this nucleotide suggest that its minor groove functionalities are important for ground-state interactions, while its major groove functional groups are critical for the chemical step of catalysis. However, the role of the catalytic triad in the group II ribozyme catalysis became fully understood only after the crystal structure of *O. iheyensis* (Oi.) intron was solved. The catalytic triad forms a triple helix, with J2/3 and one of the bulge nucleotides

(the 'catalytic triplex'), which helps create a negatively charged metal-binding pocket that harbors two magnesium ions with a potential role in catalysis.

A combination of phylogenetic analysis and biochemical studies revealed a series of long-range tertiary contacts involving DV. The GNRA tetraloop capping DV docks into a conserved 11-nucleotide receptor in DI (ζ - ζ'). In both IIA and IIB introns, DV is capped by a GNRA tetraloop. Interestingly, in IIC introns, a GANC tetraloop, which forms a novel type of interaction with its cognate receptor in DI, is found. The architecture of a GANC tetraloop is slightly different from the canonical GNRA tetraloop. The sugar pucker of its leading G residue is in a C2'-endo conformation instead of the more common C3'-endo. This results in the first base of the tetraloop being shifted to the minor groove of the helix, as opposed to the GNRA tetraloop structure, in which the first base stacks on the closing base pair. Consequently, the second through fourth bases of the GANC tetraloop stack on the closing base pair, instead of being pushed to the minor groove like in a GNRA tetraloop. These differences make it impossible for a GANC tetraloop to be inserted into receptor, in the same manner, as observed for a GNRA tetraloop-receptor interaction. The receptor structure is also different from that of a canonical 11-nucleotide motif. It is reduced to a three-nucleotide motif that does hydrogen-bond with the tetraloop but does not form the canonical AA-platform motif. In addition, three nucleotides, which in other introns belong to the ζ receptor, form a ribose zipper ω - ω' interaction with tandem sheared base pairs in a distal part of DI (close to EBS1 and α'). These interactions appear to be unique to the group IIC introns.

In addition to the ζ - ζ' contact, DV forms two more tertiary contacts with DI: κ - κ' and λ - λ' . The former, possessing some GNRA-like characteristics, plays a primarily structural role by helping position DV in the active site of the ribozyme. The latter, forming minor groove base triples, brings together catalytically important elements in DI and DV and helps anchor the 5'-splice site in the ribozyme active-site.

Domain VI

The main function of DVI is presenting the branch-point adenosine, which serves as a nucleophile in the branching pathway of the first step of splicing (Figure 2(a)), to the active site of the group II ribozyme. Branching occurs with exceptionally high fidelity; mutations designed to disrupt correct recognition of the branch site by the active site of the ribozyme generally result in impaired rather than cryptic branching. Surprisingly, aside from the branch-point adenosine, DVI is not very conserved. It has been proposed that correct selection of the branch site is determined by three factors: local geometry of the branch site, which is generally located below a conserved G-U pair, length of the DVI basal stem, and length of the linker between DV and DVI (J5/6). Recent UV-cross-linking studies have identified a purine-rich asymmetric internal loop between stems d'' and d''' (coordination loop) as a receptor for the branch site. The same study has also demonstrated that the branch site is located close to the 5'-splice site and J2/3 connecting DII and DIII, which is consistent with its role as a nucleophile in the first transesterification. A substructure similar to the coordination loop in IIB introns is also observed in

group IIC introns, although no information is available about its possible interaction with DVI. Intriguingly, there is no obvious alternative for the coordination loop in IIA introns, suggesting that they may use a different mechanism of the branch-point recognition.

Three-Dimensional Architecture and Structural Features of Group II Introns

Over 20 years have passed since the discovery of group II introns to the first crystal structure of this large ribozyme, which was solved by Pyle and co-workers in 2008. In the meantime, researchers relied on three-dimensional models obtained by using distance constraints from phylogenetic covariation and biochemical experiments. Although these models were successful in accurately positioning many of the key active-site elements, they could not depict the ribozyme active site at atomic resolution and predict all the tertiary interactions comprising the catalytic core. This void was finally filled by the crystal structure of the *Oi*. group IIC intron. It provides an invaluable insight into the overall three-dimensional organization of this intron class as well as the role of critical active-site elements.

As predicted previously from biochemical studies, the active-site elements are deeply internalized within the intron structure and protected by an outer shell formed by coaxially stacked helical regions of DI and DIII and basal stem of DII (Figure 3). DII and DIV are oriented away from the active site, which is consistent with their dispensable role in splicing. One of the key elements of the intron structural organization is the five-way junction in DI, which positions DI helices to form long-range tertiary interactions and create a scaffold for docking of other domains. This is consistent with previous findings, which identified many functionalities in this substructure as critical for intron folding. One of the most interesting features of the five-way junction is a T-loop motif, which is formed by the loop capping IA stem and intercalating adenosine residue A245 in JD/I (Figure 3). The T-loop forms a network of stacking interactions, which define the architecture of the junction. However, the most striking of all newly discovered motifs is the z-anchor, which is formed by bulged nucleotides 106–111 of subdomain IC and includes ϵ - ϵ' and λ - λ' contacts (Figure 3). It has been named 'z-anchor' because of two 160° kinks in the backbone between residues 109 and 111, which cause bases to alternate from side to side. This extended motif brings together DV, internal loop of stem I in DI and beginning of the intron, thus creating the active site. In addition to new motifs, the crystal structure confirmed the existence of predicted long-range tertiary contacts such as θ - θ' and the kissing-loop interaction α - α' .

Co-crystallization of the *Oi*. intron with exonic substrate helped elucidate exon recognition and coordination of metal ions in the ribozyme active site. The structure reveals the presence of two metal ions located at a 3.7-Å distance from each other in the catalytic core of the ribozyme (Figure 3), which is consistent with a two-metal ion mechanism of the group II intron catalysis. As these ions coordinate directly to the scissile phosphate of the ligated exons mimic, this suggests that these metals are involved in the catalytic mechanism.

Roman numerals and Greek letters indicate domains and tertiary interaction partners, respectively. Color code is the same for both panels. Disordered nucleotides are shown in black. The atomic coordinates were published in Toor N, Keating KS, Taylor SD, and Pyle AM (2008) Crystal structure of a self-spliced group II intron. *Science* 320: 77–82; and Toor N, Rajashankar K, Keating KS, and Pyle AM (2008) Structural basis for exon recognition by a group II intron. *Nature Structural and Molecular Biology* 15: 1221–1222.

Group II Intron Folding and the Role of a Protein Cofactor

For a long time, it was assumed that characterizing the higher-order structure of group II introns might be impossible due to their size and their apparent instability. However, during the past 10 years, significant progress has been made in describing the architecture as well as the folding pathway of group II introns. Most of the work focused on the yeast mitochondrial group IIB intron *coxI/ai5γ*.

The Autonomous Folding Pathway of *ai5γ* Ribozyme *In Vitro*

Although protein cofactors are essential for intracellular structure formation of group II introns, these RNAs can fold autonomously *in vitro*. Thus far, only the maturase-less *ai5γ* intron has been subjected to detailed kinetic and equilibrium folding analyses at both non- and near-physiological conditions. A ribozyme derived from *ai5γ* folds directly to the native state through an ordered, hierarchical pathway devoid of kinetic traps. This ribozyme collapses slowly to a transient intermediate in DI, while subsequent docking of other intron domains is rapid (Figure 4(a)). A small substructure in DI, the κ - ζ element, which is also the DV docking site, was found to induce the DI collapse. The compact conformation is then locked in by intradomain interactions (α - α' , β - β'), allowing subsequent docking of DIII, DV, and DVI, thereby completing intron assembly. Folding of the κ - ζ element itself is stabilized by Mg^{2+} ions through a tertiary capture mechanism. The folding pathway was recently refined by a smFRET study, in which a novel intermediate (F) during transition from the I to N state was identified. Under near-physiological conditions,

the D1356 ribozyme collapses even more slowly to a compact, near-native state, but it is incapable of forming and/or maintaining the native, splicing-competent conformation (Figure 4(b)). This is consistent with a lack of splicing under such low-salt conditions.

Protein-Facilitated Group II Folding and Splicing

Group II intron splicing factors can be divided into two categories: intron-encoded maturases and host-encoded proteins. In the past 30 years, an incredible diversity of proteins that are recruited to assist intron splicing was identified. Most of these factors promote splicing indirectly. One prominent example is Mrs2p, which is a Mg^{2+} transporter and modulates the Mg^{2+} ion concentration in yeast mitochondria. However, only a handful of proteins with a direct role in splicing have been described. Our understanding of how such proteins assist intron folding and in turn splicing is almost exclusively limited to the studies on the nuclear-encoded protein Mss116p, which is essential for splicing of all yeast mitochondrial introns.

Mss116p belongs to the DEAD-box helicase family, which are known to be nonprocessive helicases and were recently suggested to be viewed as ATP-dependent RNA-binding proteins. Indeed, Mss116p displays unwinding and annealing activity *in vitro* and lowers the Mg^{2+} requirements for group II intron splicing *in vitro*. Notably, the ATPase activity of Mss116p is required to promote intron splicing, but it is still a matter of debate whether the helicase activity is critical for this process as well. Two different models have been proposed to explain Mss116p's role in *ai5γ* splicing. One model suggests that the protein acts in an RNA chaperone-like fashion by unwinding misfolded off-pathway intermediates. Alternatively, Mss116p

Figure 4 Folding of the ai5 γ intron *in vitro*. The ai5 γ folding pathway is depicted (a) at nonphysiological conditions, (b) at near-physiological conditions, or (c) in the presence of the DEAD-box helicase Mss116p. The cylinders represent individual intron elements. For simplicity, we only sketched DI in dark gray, DIII in light gray, and DV in black, while DII and DIV are in white and DVI and the exons were omitted. Mss116p is represented as an ellipse. The unfolded, compact intermediate, folded, and native states are abbreviated as U, I_c, F, and N, respectively. Notably, as the F state has not been studied at near-physiological conditions or in the presence of Mss116p, this state is hypothetical and therefore put in brackets.

might act more like a general RNA-binding protein and may in some cases stabilize folding intermediates. While the first reports on Mss116p's mechanism of action used kinetic assays to measure native state formation as a function of catalysis *in vitro*, no structural evidence was available until this year. First, it was shown that Mss116p accelerates the collapse of ai5 γ to the compact near-native state (U $\leftrightarrow$ I), in an ATP-dependent manner, by stabilizing early folding intermediates (Figure 4(c)). However, Mss116p does not stabilize the ai5 γ native state, but such stabilization is obtained from exon binding. ATP hydrolysis is required for recycling of the protein and Mss116p's release of the compact intron might be required to allow completion of intron assembly. Strikingly, the Mss116p-promoted ai5 γ folding pathway is highly reminiscent of that in the presence of high salt. The finding that a protein known for unwinding of RNA is also able to stabilize RNA structure broadens the spectrum of how DEAD-box proteins are able to shape RNA folding landscapes, and to influence RNP architecture and rearrangements – specifically in light of the potential function of helicases in nuclear intron splicing including the spliceosome assembly pathway.

Are Group II Introns and the Spliceosome Related?

The spliceosome is a large RNP machinery composed of snRNAs and a myriad of proteins and is essential for splicing of nuclear introns, which are not catalytically active (except for

some autocatalytic group I introns present in the nucleus of a few lower eukaryotes). Years ago, it was hypothesized that group II introns and the spliceosome share a common ancestor. This was mainly based on the mechanistic similarities of spliceosomal splicing and the branching pathway of group II introns, in which the introns are released in the lariat form (Figure 2). In group II introns, key elements of the active site are the catalytic triad AGC and the dinucleotide bulge of DV, as well as the junction J2/3 (Figure 5(a)), which from a triple helical scaffold. Counterparts of these essential elements are found in the spliceosome: The AGC triad is located in the U6 internal stem-loop (ISL), which is formed in the U2/U6 snRNA complex and resembles the group II intron catalytic center DV. The conserved ACAGAGA box, which is neighboring the ISL, is considered to be the J2/3 equivalent and plays crucial role at different stages in splicing. A tertiary interaction between the last G of the ACAGAGA sequence and the bulged A between helices 1a and 1b (containing the AGC triad) has also been proposed. Another important piece of evidence for a possible evolutionary relationship between group II introns and the spliceosome is the fact that the group II intron DV can functionally replace the U6atac ISL in an *in vivo* splicing assay. Despite all these commonalities, the evolutionary link between the spliceosome and autocatalytic group II introns remains an open question. In particular, it is still a matter of debate whether the spliceosome is indeed a ribozyme. Aside from snRNAs being the catalyst, it is also possible that the protein Prp8, which is located at the spliceosome active-site and has an

Figure 5 Key elements of the group II intron active site and their counterparts in the spliceosome. (a) DV, containing the AGC triad (white filled letters), and J2/3 (gray) of the *ai5γ* intron are shown. These highly conserved elements form a triple helix in the *Oi*. group IIC intron crystal structure (equivalent interactions that could potentially form in the *ai5γ* intron are indicated by dashed lines). (b) The *Saccharomyces cerevisiae* U6 internal stem-loop (ISL), which harbors the AGC triad (white filled letters), and the ACAGAGA box (gray), which is located upstream of the ISL, are shown. An interaction (dashed line) between the last G residue of this conserved box and the A of the dinucleotide bulge separating the U2/U6 intermolecular helices 1a and 1b had been identified.

RNase H-like fold, is the enzymatically active subunit of the spliceosome. Alternatively, it has also been suggested that the spliceosome might have two active sites, one composed of RNA and the other one of protein residues, each one responsible for a distinct step in splicing.

Conclusion

The atomic-resolution structure of a group II intron represents a major breakthrough that is likely to have the field undergo a significant boost in the coming years. In particular, it will be of great interest to obtain more detailed information on the conformational rearrangement during splicing. Also, the crystallized intron belongs to the IIC family, which is considered to be the ancestral type and is much smaller than IIA and IIB introns, possessing both unique and conserved structural features. Therefore, more structural highlights remain to be discovered. Since proteins assist group II splicing *in vivo*, the next challenge will be to obtain insights into the conformation of an intron complexed with its protein partner, such as a maturase or host-encoded splicing factor, at atomic level. As of now, there are no high-resolution structures of large spliceosomal components. Undoubtedly, the field will benefit from ongoing and future efforts to explore RNA–RNA and RNA–protein interactions, as well as associated rearrangements and dynamics within the spliceosome. Eventually, the open questions of whether the spliceosome is an RNA or protein enzyme and whether the splicing systems are indeed evolutionary-linked will be answered.

Glossary

Adenosine-to-inosine (A-to-I) editing The C6 deamination of adenosine (A) to yield inosine (I), which is recognized as G rather than A, and hence represents a kind of base substitution RNA editing.

Cytidine-to-uridine (C-to-U) editing The C4 deamination of cytidine (C) to yield uridine (U), which is a kind of base substitution RNA editing.

Deamination editing Base modification involving the replacement of the amino group of adenosine (A) with oxygen from water to generate inosine (I), or in the case of cytidine (C) to generate uridine (U).

Edited RNA RNA transcript in which the RNA nucleotide sequence differs from that of the encoding genome template sequence at one or more sites, either by base substitution or by nucleotide insertion/deletion.

RNA editing The process of posttranscriptional modification of an RNA nucleotide sequence by base substitution or by nucleotide insertion/deletion.

Unedited RNA RNA transcript in which the nucleotide sequence corresponds to that encoded by the genome template.

RNA editing is the posttranscriptional modification of an RNA nucleotide sequence at one or more positions. There are two general types of RNA editing, viz., substitution editing and insertion/deletion editing. RNA editing of either type leads to the formation of transcripts whose sequence differs from that of the genome template. Such RNA sequence differences between mature transcript and encoding genome represent a form of genetic recoding. The sequence changes generated by RNA editing are different from those arising from 5'-capping, 3'-polyadenylation, and splicing, additional RNA processing events that may also occur as part of mRNA biogenesis. RNA editing is widely observed in eukaryotic organisms and their viruses. Editing, like splicing, represents a form of processing that has the capacity to amplify genetic diversity and alter gene product function by modifying the information transfer process at the posttranscriptional level of gene expression.

Discovery of RNA Editing

RNA editing was discovered in a unicellular protozoan. The frameshifted cytochrome oxidase *coxII* transcript of trypanosome mitochondria was found to contain four inserted uridines that were not encoded by the genomic DNA. Then editing by nucleotide substitution was discovered in two mammalian messenger RNAs. The apolipoprotein B (apoB) mRNA in mouse intestine had a translation stop codon at a position in the mature mRNA, whereas the genomic DNA specified the amino acid glutamine; and the glutamate-gated ion channel (GluR-B) mRNA in mouse brain had the amino acid arginine in place of the genome-encoded glutamine at the same position. Several biochemical mechanisms have been shown to account for the various RNA editing events subsequently identified in a range of mRNA transcripts. These include A-to-I substitution editing; C-to-U substitution editing; U insertion/deletion editing; C insertion editing; and G insertion editing. In addition, 2'-O-methyl ribose nucleotide modification and uridine to pseudouridine conversion represent editing events

mediated by complexes of small nucleolar RNA (snoRNA) cofactor guides and associated proteins that modify ribosomal RNAs and other RNAs. This article focuses on A-to-I and C-to-U RNA editing that occur by selective RNA-specific deamination reactions that result in nucleotide substitutions. Genetic recoding by such substitution editing can produce gene products with altered sequence and hence altered function.

Adenosine-to-Inosine Substitution RNA Editing

RNA Substrates That Undergo A-to-I Editing

RNA editing by adenosine (A)-to-inosine (I) substitution is catalyzed by C6-adenosine deaminases that act on RNA substrates with double-stranded character (Figure 1(a)). A-to-I editing occurs in several eukaryotes including *Caenorhabditis* (nematode worm), *Drosophila* (fruit fly), and *Xenopus* (frog) in addition to mammals and their viruses. Among mammalian RNAs, transcripts in the brain that encode neurotransmitter receptors for L-glutamate and serotonin represent two of the best-understood cases of A-to-I editing. This is illustrated by the α -amino-3-hydroxy-5-methyl-isoxazole-4-propionate (AMPA) glutamate receptor subunit B (GluR-B). Exon 11 in unedited GluR-B transcripts possesses a genome-encoded glutamine (Q) codon (CAG). This exon codes for a hydrophobic domain (TM2) that loops into the cell's cytoplasmic membrane. The edited GluR-B mRNA possesses an arginine (R) codon (CIG) at the same codon position, because I is recognized as G by decoding ribosomes during the translational process. Editing at this site, known as the Q/R site, occurs almost completely in the brain of adult rodents. Q/R editing of GluR-B affects channel subunit assembly in a manner that results in reduced permeability to Ca^{2+} ions. A second A-to-I editing site in GluR RNA, termed the R/G site, involves the conversion of a genome-encoded arginine (R) codon (AGA) to a glycine (G) codon (IGA) in exon 13 of edited GluR-B, -C, and -D subunit transcripts. Editing at the R/G site controls the kinetic

Figure 1 Substitution RNA editing by hydrolytic deamination. (a) A-to-I RNA editing involves the C6 deamination of adenosine to generate inosine catalyzed by ADAR enzymes. (b) C-to-U RNA editing involves the C4 deamination of cytidine to generate uridine catalyzed by APOBEC enzymes.

properties of AMPA receptor channels and leads to faster recovery rates from receptor desensitization.

Editing of GluR-B occurs at the pre-mRNA level within the nucleus, prior to splicing. RNA elements dictate the specificity of editing at the Q/R and R/G sites. The elements consist of unique *cis*-acting complementary inverted repeat sequences that are present in the intron adjacent to the exon possessing the edited adenosine. For the Q/R site in exon 11, the inverted repeat in intron 11 is predicted to form an imperfect duplex structure spanning the edited A at the Q/R site. A similar duplex RNA structure also exists within exon 13 containing the R/G site and the proximal portion of the adjacent intron 13. These exon-intron double-stranded RNA structures are absolutely essential for efficient editing at the Q/R and R/G sites of GluR-B.

The serotonin (5-hydroxytryptamine)-2C receptor (5-HT_{2c}R) provides another example of a neurotransmitter receptor whereby A-to-I editing of the pre-mRNA prior to splicing leads to amino acid substitutions in the encoded protein that alter activity. In the case of rat 5-HT_{2c}R pre-mRNA, four selective A-to-I editing sites denoted A, B, C, and D have been identified in exon 3 that specify three amino acid substitutions. The 5-HT_{2c}R genomic sequence specifies the transcript sequence ...AUA CGU AAU CCU AUU... that encodes ...*ile*-*arg*-*asn*-*pro*-*ile*... in the unedited RNA. Editing of the four sites leads to the sequence ...IUI CGU AIU CCU IUU... in fully edited RNA that encodes ...*val*-*arg*-*ser*-*pro*-*val*... in the receptor protein product. The three amino acid substitutions shown in italics created by A-to-I editing of 5-HT_{2c}R transcripts occur in the putative intracellular loop II of the receptor and they cause

a reduction in G-protein-mediated signaling. Here again, the selective editing of 5-HT_{2c}R pre-mRNAs is dictated by imperfect inverted repeat sequence that forms an RNA duplex between the 3'-end of exon 3 spanning the four editing sites and the 5'-end of the adjacent intron-3.

One of the challenges of A-to-I editing is to identify additional substrates. The GluR-B and 5-HT_{2c}R substrates in rodents and humans were identified serendipitously, and indeed so far such A-to-I editing events that give rise to recoding of translated sequences appear to be rare. Bioinformatic approaches for analysis of the human transcriptome, using cDNA and expressed sequence tag databases and the human genome sequence, identified several thousand candidate A-to-I editing sites. Most of these sites occur in noncoding regions of RNA, often in short repetitive Alu elements of intronic and 3'-untranslated regions of RNAs. The functional significance of A-to-I editing of Alu elements is not yet fully understood.

Editing sites have also been identified in another class of noncoding RNA, the microRNAs (miRs) and their precursors. In RNA interference (RNAi), miRs function as regulatory RNAs that can downregulate with high specificity the production of a targeted protein gene product through either mRNA degradation or translational suppression. A-to-I RNA editing can affect RNAi at two levels. A-to-I editing can impair the processing of miR precursor RNAs by the Dicer and Drosha nucleases of the RNAi machinery, thereby altering the amount of miR RNA produced. A-to-I editing can also alter the sequence of the mature miR product by substitution of I (G) for A, thereby leading to a different mRNA targeting in the RISC complex.

Adenosine Deaminases That Act on RNA

A-to-I editing events of substrates such as GluR-B and 5-HT_{2c}R are catalyzed by a multigene family of enzymes known as ADARs adenosine deaminases that act on RNA. Three mammalian genes are known to encode ADARs, two of which are catalytically active deaminases. ADAR1 and ADAR2 efficiently deaminate both synthetic and naturally occurring double-stranded RNA substrates. The ADAR1 and ADAR2 enzymes possess different activities for the different sites in the GluR-B and 5-HT_{2c}R transcript RNAs. ADAR2 deaminase efficiently edits the Q/R site of GluR-B, while the ADAR1 enzyme possesses little editing activity at Q/R. Both ADAR1 and ADAR2, however, are capable of editing the R/G site of GluR-B. For 5-HT_{2c}R pre-mRNA transcripts in rat brain, ADAR1 very efficiently edits the A site but is inactive for the D site, whereas ADAR2 efficiently edits the D site. ADAR1 and ADAR2 possess multiple copies of a canonical double-stranded RNA-binding motif (R, dsRBM) that are located in the central region of the ADAR proteins (Figure 2). The interferon inducible form of ADAR1 possesses, in addition to three dsRNA-binding motifs, two copies of a Z-DNA-binding motif (Z α and Z β) in the N-terminal region of the protein. The dsRNA- and Z-DNA-binding motifs of ADAR1 are distinct from the deaminase catalytic domain located in C-terminal region of the ADAR proteins. The dsRNA-binding motifs are presumed to play a role in the binding of substrate RNAs, but it is also possible that they play a role in regulation of enzymatic activity. For

Figure 2 Schematic structure of human RNA-specific deaminases. ADAR1 and ADAR2 possess double-stranded RNA-binding (R) motifs (red) and Z-DNA-binding motifs (pink). The RNA-binding motif of APOBEC1 overlaps with the catalytic domain. The catalytic domains of ADAR and APOBEC are shown in yellow. Two size forms of ADAR1 are expressed, the larger p150 form that is interferon inducible and the smaller constitutively expressed p110 form. While ADAR2 and APOBEC1 are not known to be regulated by cytokines or growth factors, both APOBEC3G and 3F are interferon inducible.

example, adenovirus VA₁ RNA, a small and highly structured viral gene product transcribed by cellular RNA polymerase III, efficiently antagonizes ADAR deaminase activity.

The expression of ADAR enzymes in cells is a complex process. For example, in the case of the *ADAR1* gene in humans and mice, alternative promoters including one inducible by interferons together with alternative exon 1 splicing give rise to two differently sized enzyme isoforms, called p150 and p110 (Figure 2). The interferon inducible form of ADAR1, the p150 or long form, is found in both the cytoplasm and nucleus of cells. The constitutive p110 or short form, which lacks the N-terminal 295 amino acids that includes the Z α -binding motif, is found predominantly if not exclusively in the nucleus. Additional ADAR protein multiplicity is achieved by alternative splicing involving downstream exons, both in the case of ADAR1 and ADAR2. The full physiological significance of the splice variants of ADAR is not known; one possibility may relate to the substrate selectivity of the enzymes.

Cytidine-to-Uridine Substitution RNA Editing

RNA Substrates That Undergo C-to-U Editing

Cytidine (C)-to-uridine (U) substitution RNA editing is catalyzed by C4-cytidine deaminases that act on single-stranded RNA substrates (Figure 1(b)). C-to-U editing has been characterized in both plants and mammals. One of the best-understood examples is the mammalian mRNA transcript that encodes apolipoprotein B (apoB) that functions in lipid metabolism. There are two forms of apoB. The larger form (apoB100) is synthesized in the liver and assembled into lipoprotein particles that are secreted into the bloodstream and are important for transport of synthesized triglycerides and cholesterol. The carboxyl terminal region of apoB100 interacts with the low-density lipoprotein

receptor to remove LDL from circulation. Editing of apoB mRNA by deamination of a single cytidine changes a genome-encoded glutamine codon (CAA) to a translation termination codon (UAA). This C-to-U editing occurs in the small intestine but not the liver. ApoB RNA editing causes the synthesis of a truncated intestinal lipoprotein known as apoB48 that lacks the C-terminal region of apoB100, but otherwise is identical to the N-terminal part (48%) of apoB100. While apoB100 is associated with LDL protein particles, apoB48 lacks receptor-binding activity and is important for transport of dietary lipids.

Editosome Complex

C-to-U editing of apoB mRNA occurs in the nucleus and is selective for spliced transcripts rather than pre-mRNAs. Deamination is mediated by a multiprotein complex called an editosome. The editosome includes a protein that possesses catalytic activity (Apolipoprotein B Editing Catalytic subunit 1, APOBEC-1) together with one or more associated proteins that include an apobec-1 competence factor (ACF), which possesses RNA recognition activity. Unlike the ADAR enzymes, APOBEC does not possess a separate canonical RNA-binding motif, but rather RNA-binding activity appears to overlap with the catalytic domain residues (Figure 2). A tripartite RNA motif that includes efficiency elements, spacer, and a mooring sequence surrounds nucleotide C6666 of apoB mRNA and appears sufficient to confer the required specificity of the C-to-U editing reaction of ApoB RNA. ACF protein binds apoB RNA selectively at the region of the editing site and interacts with APOBEC-1 deaminase to mediate C-to-U editing activity. Multiple splice variants of the ACF protein are found in different human tissues, but their functional significance remains unknown. Similarly, several homologs of the APOBEC-1 have been identified, including ARCD1/APOBEC-2, AID, and phorbolin/ARCD2-7/APOBEC-3A to G.

The existence of multiple APOBEC-1 homologs and ACF variants suggests additional substrates and physiologic roles for C-to-U editing beyond that apoB mRNA. Two examples include C-to-U RNA editing by APOBEC-1 associated with a malignant phenotype, and dC-to-dU editing of viral DNA by APOBEC-3 cytidine deaminases that act as DNA mutators. In the example of the cancer, the cellular mRNA for the neurofibromatosis type 1 (NF1) protein encoded by NF1 tumor suppressor gene undergoes selective C-to-U RNA editing. The encoded NF1 protein, neurofibromin, functions as a Ras-GTPase-activating protein (GAP). Site-specific deamination of a cytidine (nucleotide C3916) in NF1 mRNA converts a genome-coded arginine codon (CGA) to a translation termination codon (UGA). The shortened NF1 open reading frame that results from this C-to-U editing has been observed in a subset of peripheral nerve sheath tumors from NF1 patients and is predicted to give rise to a truncated neurofibromin protein product deficient in GAP activity.

Substitution Editing of Viral RNAs

RNA editing may play a significant role in viral pathogenesis and affect the host response to viral infection. A number of viral RNAs, including those of avian leukosis virus (ALV), hepatitis delta virus (HDV), hepatitis C virus (HCV), human

herpes virus 8 (Kaposi sarcoma virus), lymphocytic choriomeningitis virus (LCMV), measles virus, and polyoma virus all show codon changes under certain infection conditions that are consistent with A-to-I editing. Among the best-characterized viral RNA substrates that undergo site-selective editing is that of HDV. Both ADAR1 and ADAR2 convert an amber translation stop codon (UAG) to a tryptophan codon (UIG) in HDV antigenomic RNA. This editing allows for the synthesis of two delta virus antigen forms, a short form used during viral replication and a long form necessary for assembly of viral particles. A-to-I editing of viral RNA genomes can also occur at multiple sites during lytic and persistent infections, giving rise to hypermutations of viral RNAs. One example of such hypermutations characteristic of A-to-I editing is that of measles virus (MV), where viral RNAs isolated from brains of persistently infected subacute sclerosing panencephalitis (SSPE) patients possess multiple sequence differences from the viral RNA genome that correspond to A-to-G and U-to-C substitution mutations. Because MV, a negative-strand RNA virus, replicates in the cytoplasm, it is presumed that ADAR1 is the responsible enzyme. A-to-I hypermutations are also seen in viral RNAs of polyoma virus, HCV and LCMV. The DNA virus vaccinia that replicates in the cytoplasm of cells encodes a protein product (E3L) that efficiently antagonizes ADAR1 deaminase activity, and mutations in E3L are known to affect viral pathogenesis in the mouse model.

Finally, C-to-U RNA editing like A-to-I editing may play a role in the interactions between viral pathogens and their hosts. Among the homologs of APOBEC-1, the APOBEC-3 family members, particularly 3G and 3F, function as innate cellular restriction factors with broad anti-retroviral activity. These deaminases catalyze cytidine deamination of retrovirus reverse transcripts that correspond to the negative-sense single-strand cDNA in infected cells. The resultant dC-to-dU deaminations lead to dG-to-dA hypermutations in viral positive-sense cDNA and the subsequent inhibition of virus growth. Although both 3G and 3F APOBECs restrict retrovirus infection, they display somewhat different sequence context specificity for deamination of deoxycytidine. Primate lentiviruses including human immunodeficiency virus (HIV-1), a retrovirus that is the cause of acquired immune deficiency syndrome (AIDS), encode a regulatory viral protein called vif that blocks the antiviral activity of the cellular APOBEC-3G and -3F proteins. Like ADAR1 p150, APOBEC-3G and -3F are both inducible by interferon. Alteration of the amount of APOBEC deaminase, accessory protein, or viral antagonist could modulate RNA editing or DNA mutator activity within cells.

Editing by Nucleotide Insertion/Deletion

A second general type of RNA editing, in addition to base substitution editing, is nucleotide insertion/deletion editing. Among the best-characterized examples of insertion/deletion editing is that of U-insertion and U-deletion. Uridine insertion/deletion editing occurs by an enzymatic cleavage-ligation mechanism. The specificity of U-insertion/deletion editing is determined by RNA-RNA base pairing between a complementary guide RNA (gRNA) and the target RNA (mRNA) substrate. The base-paired

RNA complex serves to position the enzymatic machinery at the site of U insertion or deletion, thereby guiding the modification process. Much has been learned from the trypanosome mitochondrial system about the features and requirements of the complementary gRNAs that act in trans to target enzyme complexes to the mRNA site of uridine insertion/deletion editing. The enzymatic cleavage-ligation mechanism of U insertion/deletion editing involves hybridization of gRNA to mRNA to form a gRNA:mRNA anchor duplex, after which the mRNA is specifically cleaved by a gRNA-dependent ribonuclease at the site of the gRNA:mRNA mismatch. For U-insertion editing, a 3'-terminal uridylyl transferase (TUTase) then adds U's to the 3'-end of the 5'-fragment guided by base pairing with the gRNA, followed by ligation of the two fragments by an RNA ligase. For U-deletion editing, a U-specific 3'-5'-exonuclease removes the bulged U residues, followed by ligation of the two RNA fragments. Finally, in addition to U-insertion editing as exemplified by the cytochrome oxidase mRNA in trypanosome mitochondria, C-insertion editing and G-insertion editing are also known to occur as illustrated by Physarum mitochondria and by negative-strand RNA viruses, respectively. In the case of paramyxoviruses including measles virus and Sendai virus, G-nucleotide insertion occurs during the RNA transcription process to generate edited P/V/C gene transcripts that include nontemplated Gs.

Roles of RNA Editing

Altering the information transfer process at the posttranscriptional level of gene expression by RNA editing represents an important strategy for amplifying genetic diversity and

Figure 3 Established and potential roles of RNA editing by deamination. Edited RNA transcripts (A-to-I; C-to-U) possess different sequences than their unedited transcript counterparts. Hence, edited RNAs may display different functional activities than the corresponding unedited transcripts. Editing may alter processes including mRNA translation, by changing mRNA codons and hence proteins encoded by them. Editing may alter pre-mRNA splicing patterns by changing splice site-recognition sequences. Editing may alter micro-RNA production or activity, by changing RNA structure or gene targeting sequence recognition. Editing may affect RNA degradation by modifying RNA sequences involved in nuclease recognition. Editing may affect viral RNA genome genetic stability by changing template and hence product sequences during RNA replication. Finally, editing potentially may affect RNA structure-dependent activities that entail binding of RNA by proteins. Adapted from Samuel CE (2003) RNA editing minireview prologue. *Journal of Biological Chemistry* 278: 1389–1390.

modifying the functions of products encoded by an organism's genome. Some of the mechanistic roles that substitution editing through A-to-I and C-to-U deamination play, or are anticipated to play, in biological processes are summarized in [Figure 3](#). These biochemical mechanisms include effects of editing on mRNA translation, pre-mRNA splicing, RNA silencing, RNA degradation, RNA replication, and RNA structure that result from nucleotide substitution via deamination or nucleotide insertions. Site-specific editing may change the coding potential of mRNA transcripts, leading to proteins with altered function due to amino acid substitutions following A-to-I editing. This is exemplified by the GluR-B and serotonin-2c receptor proteins. Introduction or removal of translation termination codons may also occur, as exemplified by apoB and NF1 mRNAs where C-to-U editing generates UAA and UGA translation termination codons respectively, and HDV RNA where A-to-I editing converts an amber UAG stop to a tryptophan codon. ADAR2 edits its own transcript, to create an alternative splice acceptor site. A-to-I editing can affect RNA interference responses, either by altering the production process and hence amount of mature microRNA or by generating a microRNA with an altered targeting sequence. A novel ribonuclease selective for inosine-containing RNAs has also been described, consistent with the notion that A-to-I edited transcripts may be degraded preferentially relative to the unedited transcripts. For viral RNAs, deaminations in either the plus- or minus-strand RNA could lead to mutations in the encapsidated viral genome sequence. Finally, sequence changes resulting from editing may subsequently affect RNA structure and function, including protein–RNA interactions such as those necessary for protein kinase PKR ([Figure 3](#)).

Glossary

Chromatin The DNA wrapped up with proteins, as found in chromosomes.

Promoter A stretch of DNA located near the transcription start site that influences the efficiency of transcription.

RNA polymerase The enzyme responsible for synthesizing RNA.

Transcription The process using DNA as template to synthesize a complementary RNA.

Transcription factor Protein that influences the ability of RNA polymerase to carry out transcription.

RNA polymerases are the enzymes responsible for synthesizing RNA, in a process called 'transcription'. They use DNA as a template, and the RNA they produce carries a faithful copy of the genetic information contained in the template. Whereas bacteria use a single RNA polymerase to transcribe all their genes, the nuclei of eukaryotes contain three. Each is responsible for transcribing a unique set of essential genes. RNA polymerase I synthesizes most of the ribosomal RNA (rRNA), RNA polymerase II synthesizes the protein-encoding messenger RNA (mRNA) and most small nuclear RNA (snRNA), while RNA polymerase III synthesizes a variety of small untranslated RNAs, including transfer RNA (tRNA) and 5S rRNA. An additional RNA polymerase is present in mitochondria, which carry a small DNA molecule of their own. This division of labor could have become necessary as genomic complexity increased during evolution. In actively growing cells, RNA polymerase I can be responsible for ~70% of all nuclear transcription, whereas RNA polymerases II and III contribute ~20% and 10%, respectively.

Genes Transcribed by RNA Polymerases I and III

Despite its very high activity, RNA polymerase I only transcribes a single type of gene, which encodes the large rRNA precursor molecule. This precursor is then processed into the mature 5.8S, 18S, and 28S rRNA components of ribosomes. A single molecule of each of these rRNAs, along with a 5S rRNA molecule and ~85 proteins, is incorporated into each ribosome. The pre-rRNA is encoded by multiple gene copies, the number of which varies between different organisms; mammals have ~150–200 copies arranged in tandem head-to-tail arrays.

The genes transcribed by RNA polymerase III are invariably very short, rarely exceeding 300 bp in length. Many of their products have essential functions, such as the 5S rRNA and tRNAs (required for protein synthesis), 7SL RNA (involved in intracellular trafficking of proteins as part of the signal recognition particle), and the U6, multidrug resistance-associated protein (MRP), and H1 RNAs (involved in the processing of mRNA, rRNA, and tRNA, respectively). Mammalian genomes also contain large numbers of short interspersed repeats

(SINEs) that are transcribed by RNA polymerase III, such as the Alu family in man. In addition, certain viruses carry genes that are transcribed by RNA polymerase III, such as the VA genes of adenovirus and the EBER genes of Epstein–Barr virus. The products of these viral genes can subvert the translational machinery of an infected cell, diverting it toward the more effective production of viral proteins.

Nucleoli

Within the nucleus, the most obvious landmarks under a light microscope are nucleoli, because of their high density. These form around the actively transcribed rRNA gene repeats and contain closely packed molecules of transcribing RNA polymerase I, each with a nascent pre-rRNA attached. Furthermore, ribosomal proteins assemble on the nascent transcript while it is being made. Although nucleoli have the appearance of organelles, they are in fact dynamic structures without membranes that disappear when transcription stops (e.g., during the general suppression of gene expression that accompanies mitosis). Transferring rRNA genes to a novel chromosomal location can result in the appearance of an ectopic nucleolus. When cells become very old, their nucleoli fragment; it has been suggested that nucleolar degeneration may be an important aspect of cellular aging.

The RNA Polymerase Molecules

RNA polymerases I, II, and III are large and complex proteins, consisting of 14, 12, and 17 subunits, respectively. Five of these subunits are shared, and a further two are found in RNA polymerases I and III, but not in RNA polymerase II. The two largest subunits of each enzyme are unique, but share substantial homology with each other and also with bacterial RNA polymerases; they fold together to provide the catalytic site of the enzyme. Besides these, RNA polymerases I, II, and III each have an additional set of unique subunits. Although most of the subunits are required for cell viability, their precise roles remain poorly characterized.

Figure 1 Simplified model of the transcription complexes used by RNA polymerases I and III. (a) UBF and SL1 assemble at the promoters of large rRNA genes and then recruit a preassembled complex containing Rrn3 and RNA polymerase I (Pol I), as well as additional factors not shown. (b) TFIIC binds directly to the promoters of most genes transcribed by RNA polymerase III, for example, tRNA genes. TFIIB is recruited by protein/protein interactions with TFIIC and then serves to bring RNA polymerase III (Pol III) to the transcriptional start site. (c) Similar events occur at 5S rRNA genes, but these are initiated by TFIIA, which binds promoter DNA and provides a scaffold for TFIIC assembly. +1 denotes where transcription initiates.

The RNA Polymerase I and III Transcription Apparatus

Despite their complexity, the nuclear RNA polymerases require considerable assistance to locate their genetic templates. Sets of transcription factor proteins assemble at promoter DNA sequences near the initiation sites of genes and then serve as molecular beacons which recruit the appropriate RNA polymerase.

For the large rRNA genes, promoter recognition is achieved by the homodimeric factor upstream binding factor (UBF) that binds across the promoter region upstream of the transcription start site. UBF bends the DNA and wraps it around itself to create a three-dimensional nucleoprotein structure that is recognized by SL1, the factor responsible for polymerase recruitment. RNA polymerase I is preassembled with a polypeptide called Rrn3 that serves as an essential bridge between the polymerase and SL1 (**Figure 1(a)**). Several additional transcription factors are also associated with RNA polymerase I and are recruited with it in a concerted manner. Although these principles apply to mammals and frogs, the machinery required for rRNA synthesis is rather different in yeast. Indeed, the RNA polymerase I transcription apparatus is much less well

conserved through evolution than those of RNA polymerases II or III; whereas human proteins can transcribe a yeast tRNA gene, they will not even recognize the large rRNA genes from mouse.

In the case of RNA polymerase III, two key transcription factors, TFIIB and TFIIC, play central roles in both yeast and man (**Figure 1(b)**). The former is responsible for recruiting RNA polymerase III and positioning it over the transcription initiation site; it also helps separate the two strands of the DNA helix, thereby facilitating the start of RNA synthesis. However, TFIIB is unable to recognize the DNA sequences of most RNA polymerase III promoters, but must be brought into position through protein-protein interactions with DNA-bound TFIIC. An unusual feature of this system is that the promoter sequences recognized by TFIIC are located downstream of the transcription start site, within the transcribed region. Although in most cases TFIIC binds directly to DNA, this is not possible for the 5S rRNA genes which have a distinct promoter arrangement. In these cases, an additional polypeptide, TFIIA, binds along the DNA and provides a protein scaffold to which TFIIC binds (**Figure 1(c)**). TFIIA contains nine tandem copies of the zinc finger DNA-binding domain. Indeed, it was the founder member of the zinc finger family, the largest group of transcription factors in organisms ranging from yeast to man (~900 members in humans).

Alu Genes and Retrotransposition

The human genome carries over a million copies of the Alu gene, which provides ~10% of our total DNA. Despite their abundance, only small numbers of Alu genes are actually transcribed, the remainder being silenced through epigenetic mechanisms, including methylation and incorporation into repressive chromatin. SINES propagate by retrotransposition, in which their RNA transcripts are copied into DNA and then inserted into novel genomic sites. These insertions occur preferentially into areas of active transcription, perhaps because of their more open and accessible chromatin structure. This increases the danger that integrating SINES will disrupt genes at the recipient loci, thereby having a mutagenic effect. Indeed, cases of haemophilia, neurofibromatosis, and breast cancer are believed to have arisen in this way. It is estimated that Alu insertions account for ~0.1% of all human genetic disorders. By contrast, retrotransposition is much more active in mice, where it may contribute ~10% of mutations.

RNA Polymerases I and III and Tumor Suppression

The RNA polymerase I and III transcription systems are both targeted directly by two key tumor-suppressor products, p53 and retinoblastoma (RB). Both these proteins bind to TFIIB and block its interactions with TFIIC and RNA polymerase III, thereby repressing transcription. RB also binds to UBF to inhibit synthesis of large rRNA, whereas p53 inactivates SL1. The ability of RB and p53 to suppress the output of RNA polymerases I and III may contribute to their capacity to restrain cell growth. RB has been described as a gatekeeper that only allows cells to grow and proliferate when conditions

are propitious. Inherited mutations in RB can cause the pediatric eye cancer RB. Indeed, it is widely believed that RB function must be compromised in some way before any tumor can develop. The most commonly mutated gene in human cancer is p53, which is famous as the guardian of the genome. If a cell's DNA gets damaged, for example, through exposure of skin to excessive doses of UV light, p53 gets activated and triggers a protective response; this can involve halting growth and cell-cycle progression until the damage has been mended or, under extreme circumstances, apoptotic death. These responses ensure that DNA-carrying potentially harmful mutations are not passed on to further generations of cells.

Links between Human Disease and RNA Polymerases I and III

RNA polymerases I and III together may contribute ~80% of nuclear transcription and provide ~95% of the total RNA in cells. This very high level of production is necessary to make the several million new ribosomes that are needed per generation to maintain protein synthetic capability. Because they are such major determinants of biosynthetic capacity, the activities of RNA polymerases I and III are closely linked to the rate of cellular growth. In hyperproliferative diseases such as cancer, there is generally an elevated rate of transcription by these polymerases. Indeed, pathologists use enlarged nucleoli (a sign of accelerated rRNA synthesis) as a diagnostic indicator of tumor formation. To a large degree, the elevated activity of RNA polymerases I and III in cancer cells is likely to reflect the inactivation of p53 and/or RB; since these tumor suppressors play a major role in restraining transcription by RNA polymerases I and III in healthy cells, their inactivation during cancer development will remove a major restraining influence and allow deregulated gene expression. These effects must be extremely widespread, since p53 is mutated in ~50% of human tumors and RB function may be compromised in all forms of malignancy. In addition to their release from these transcriptional repressors, the output of RNA polymerases I and III is also increased in some cancers through the action of certain oncogenic proteins. An example is c-Myc, which is deregulated in many tumor types and is believed to contribute to one in seven US cancer deaths. TFIIB is bound and activated by c-Myc, leading to elevated rates of RNA polymerase III transcription. Certain types of cancer also produce abnormally high levels of the transcription factors used by RNA polymerases I and III. For example, UBF is frequently overexpressed

in hepatocellular carcinomas, whereas TFIIC is unusually abundant in ovarian tumors.

Epstein–Barr virus is associated with gastric and nasopharyngeal carcinomas, Burkitt's lymphoma, Hodgkin's disease, and acquired immuno-deficiency syndrome (AIDS)-associated lymphoma. Its most highly expressed gene products are the EBER RNAs, which are synthesized by RNA polymerase III. The presence of these transcripts is used diagnostically as a test for Epstein–Barr virus. Indeed, very few other viral genes are expressed in Burkitt's lymphomas. Recent studies have shown that the EBER1 transcript can be sufficient for oncogenic transformation, a remarkable fact since it is only 167 nucleotides long. This provides the first reported example of an untranslated RNA that can transform cells.

An inherited-developmental disorder has been shown to result from mutations in the MRP gene that is transcribed by RNA polymerase III to produce a short RNA that is required for mitochondrial replication and for the processing of large rRNA. Families afflicted with this condition suffer from cartilage–hair hypoplasia, a complex syndrome involving short stature (adult heights of 104–149 cm), abnormal cartilage, and hypoplastic hair, sometimes with a compromised immune system. This disorder is especially common amongst the Old Order Amish of Pennsylvania.

Glossary

Basal transcription factors Minimal set of auxiliary transcription factors required to support promoter-specific transcription initiation by polymerase II (pol II).

DNA helicase Enzyme that uses the energy of adenosine triphosphate (ATP) hydrolysis to unwind the two strands of DNA.

DNA template DNA that is transcribed by RNA polymerases.

Promoter DNA sequences that direct RNA polymerases to transcribe genes.

RNA polymerase Enzyme that catalyzes synthesis of RNA.

Synthesis of eukaryotic messenger RNA (mRNA) is catalyzed by RNA polymerase II (pol II). A set of five general transcription factors (GTFs) designated transcription factor IIB (TFIIB), TFIID, TFIIIE, TFIIF, and TFIIFH interact to promote binding of RNA pol II to gene regulatory sequences termed promoters and assist in the initiation of RNA synthesis.

RNA Pol II Structure and Function

RNA pol II is one of three multi-subunit DNA-dependent RNA polymerases present in all eukaryotic cells. Pol II transcribes mainly protein-coding genes, while pol I and pol III transcribe ribosomal RNA genes and small noncoding RNA genes, respectively. Transcripts formed by pol II in the nucleus are subsequently capped, spliced, polyadenylated, and transported to the nucleus where they are translated by ribosomes to form proteins.

Pol II is a multi-subunit enzyme of about 500 kDa that is highly conserved from simple to complex organisms. The catalytic mechanism of pol II has been determined from examination of high-resolution X-ray crystal structures of *Saccharomyces cerevisiae* pol II.

Rpb1 and Rpb2 are the largest subunits and they form the core of the enzyme with smaller subunits arranged around the surface. The main feature of the enzyme is a deep channel where RNA is synthesized. Approximately 12 bp of DNA are unwound during transcription and the single-stranded template is buried in this central channel where it forms a hybrid with approximately nine nucleotides at the 3'-end of the growing RNA chain. The nontemplate DNA strand is displaced to the surface of the enzyme. This arrangement creates a single-stranded bubble of DNA that slides through and around the central channel of the polymerase as DNA base pairs are progressively unpaired in front of the enzyme and then reform after transcription.

At the base of the channel is the active site of the polymerase that catalyzes the formation of phosphodiester bonds between the growing 3'-end of the transcript and an incoming ribonucleoside triphosphate (NTP). Selection of the correct NTP is determined by base pairing with the single-stranded DNA template in the active site. The catalytic site contains two magnesium ions, one chelated by aspartate residues in the

enzyme and the other by phosphates on the incoming NTP. The magnesium ions facilitate a nucleophilic attack of the 3'-hydroxyl of the transcript on the α -phosphorus of the substrate NTP. Formation of the phosphodiester bond is coupled with release of a pyrophosphate and translocation of the polymerase along the substrate placing the new 3'-hydroxyl in the active site. As the enzyme advances, nascent RNA starting about 10 bases downstream of the growing end is removed from the RNA:DNA hybrid and exits the polymerase through a small channel. The elongating pol II complex is extremely stable because after transcription starts the polymerase undergoes a conformational change clamping the template in the central channel.

Pol II Core Promoters

DNA sequences that signal the start of pol II transcription vary widely from gene to gene with the most common sequences constituting a core promoter that surrounds the transcription start site. The core promoter serves to orient pol II on the DNA and directs accurate initiation. Several different core promoter elements have been identified and some combination of these elements is present on many, but not all, pol II promoters. The TATA box contains the sequence TATA(A/T)A(A/T) and in metazoans is located 25–30 nucleotides upstream of the transcription start site. A second common core promoter element is the initiator (Inr) that contains a pyrimidine-rich consensus sequences YYAN(T/A)YY, where Y is a pyrimidine, N can be any of the four bases A, C, G, or T, and the first A is the transcription start site. The downstream promoter element (DPE) with a consensus (A/G)G(A/T)CGTG is located about 30 nucleotides downstream of the transcription start site. Some promoters contain none of these elements but may contain less common core promoter sequences such as the motif ten element, the downstream core element, or the TFIIB-responsive element.

Core promoters are insufficient for pol II initiation *in vivo* and most genes contain additional regulatory elements for one or more DNA-binding regulatory proteins. These gene-specific activators or repressors control frequency of initiation at the core promoter. Regulatory sequences within a few hundred nucleotides of the core promoter are called promoter proximal

elements, while more distal regulatory sequences, termed enhancers or silencers, can be located thousands of base pairs from the core promoter.

Pol II GTFs

Pol II alone is unable to initiate transcription and requires a set of auxiliary proteins termed GTFs including TFIIB, TFIID, TFIIF, TFIIE, and TFIIH. The GTFs work in a multistep process that begins with the assembly of a pol II pre-initiation complex at the core promoter. In the first step, TFIID binds to the core promoter setting up a DNA–protein complex that directs transcription in the proper orientation starting at the correct site. TFIID is a multi-subunit protein containing the TATA-box binding protein (TBP) and as many as 13 additional proteins designated TBP-associated factors (TAFs). TBP binds directly to the TATA box when present but is able to recognize a wide range of related sequences. TAFs also interact specifically with the core promoter DNA with TAF2 binding the Inr and TAF6 and TAF9 recognizing the DPE. In the next step of pre-initiation complex assembly, TFIIB recruits pol II to the TFIID–core promoter complex. TFIIB is a single polypeptide with several domains that interact independently with pol II and TFIID. The TFIID–TFIIB–polII complex is stabilized by the binding of TFIIF, which is required for the subsequent binding of TFIIE and then TFIIH to form the final pre-initiation complex. TFIIH is a nine-subunit factor containing both helicase and protein kinase activities.

Mechanism of Pol II Initiation

The fully assembled pre-initiation complex contains about 40 polypeptides bound on the core promoter DNA. The multiple DNA-binding proteins in this complex result in the DNA bending at the site of TBP binding, thereby positioning TFIIH near the start of transcription. A helicase activity present in TFIIH uses adenosine triphosphate (ATP) to unwind the core promoter DNA, resulting in a short segment of single-stranded template DNA entering the pol II active site channel. TFIIB interacts with this DNA, stabilizing the transcription bubble and assisting the positioning of the transcription start site in the pol II active site. Pol II then synthesizes the first few phosphodiester bonds resulting in a short transcript that remains bound to the DNA template. After the synthesis of about 10 bases, the 5′-end of the RNA chain is removed from the DNA:RNA hybrid and enters the RNA exit channel. At this point, the function of the GTFs is complete and pol II leaves the pre-initiation complex and begins the process of elongation. The nascent 5′ end of the mRNA is capped as it emerges from the RNA exit channel.

Termination of Pol II Transcription

Pol II transcripts generally span a single gene. The elongating pol II eventually reaches the end of the protein-coding region where it transcribes a sequence that signals the cleavage and subsequent polyadenylation of the nascent pre-mRNA. Cleavage of the nascent transcript separates the transcript from the elongation complex, leaving pol II with a short RNA containing an unprotected 5′-end. Exonucleases degrade this un-capped RNA more rapidly than pol II can elongate, thus leading to an unstable elongation complex that dissociates from the template DNA.

Conservation of Pol II and the GTFs

Pol II is one of three multi-subunit RNA polymerases common to all eukaryotes. These three polymerases are highly related to each other and to archaeal and bacterial RNA polymerase, especially in the regions of the largest subunits that constitute the active site. In addition, several of the smaller eukaryotic RNA polymerase subunits are shared by more than one type of polymerase, whereas bacterial RNA polymerase uses sigma factors to assist in the initiation reaction eukaryotes and archaea employ GTFs. Archaea use only three GTFs: TBP, TFIIB, and TFIIE. The genomes of eukaryotes encode the full complement of GTFs and, in addition, have additional genes encoding variants of the GTFs. For example, the human genome encodes several variants of TBP that can recognize different types of core promoters.

Glossary

DRB The P-TEFb inhibitor 5,6-dichlororibofuranosyl benzamidazole.

DSIF DRB sensitivity inducing factor, an N-TEF.

NELF Negative elongation factor, an N-TEF.

N-TEFs Negative transcription elongation factors.

P-TEFb Positive transcription elongation factor b composed of Cdk9 and a cyclin partner.

During the 1990s, it became clear that the elongation properties of RNA polymerase II are regulated and the factors responsible play a critical role in controlling gene expression in eukaryotic cells. One set of factors helps RNA polymerase II to negotiate pause and arrest sequences in the template, and to maintain an elongation rate of 1000–1500 nucleotides per minute. The initiation factor TFIIF (transcription initiation factor IIF) reduces RNA polymerase II pause times and stimulates the rate of elongation. The elongation factor S-II or transcription initiation factor IIS (TFIIS) rescues polymerase molecules that are blocked from further elongation at arrest sites. Another set of factors is responsible for an elongation control process that regulates the fraction of initiated polymerases that enter productive elongation to generate messenger RNAs (mRNAs). Negative transcription elongation factors (N-TEFs), such as 5,6-dichlororibofuranosyl benzamidazole (DRB) sensitivity inducing factor (DSIF) and negative elongation factor (NELF), slow the rate of elongation and restrict the polymerase to promoter proximal sequences. The positive transcription elongation factor, P-TEFb, overcomes the effect of the negative factors and allows the production of full-length transcripts. The function of P-TEFb is regulated through interactions with many other transcription factors and the amount of active P-TEFb in the cell is precisely regulated through a reversible inhibition by the small cellular RNA, 7SK.

Historical Perspective

It has been clear for some time that much of the regulation of prokaryotic gene expression is accomplished by controlling the elongation potential of RNA polymerase, but only recently has it become apparent that eukaryotic gene expression is similarly regulated. Early work in John Lis's lab showed that there was an RNA polymerase II molecule engaged in transcription of the major *Drosophila* heat shock gene, HSP70, under conditions where no full-length mRNAs were being produced. Only after heat shock were the polymerases allowed to continue elongation and produce mRNAs. Similarly, regulated premature termination of transcription was seen on a number of viral genes, most notably from human immuno-deficiency virus (HIV), as well as on cellular genes, including oncogenes such as c-myc and c-fos. In the early 1990s, *in vitro* systems were beginning to reproduce the elongation control process and ultimately these

systems allowed the identification and purification of some of the specific factors involved. The current model of RNA polymerase II elongation control has the look and feel of models of prokaryotic antitermination, but there are important differences in mechanistic details.

Positive and Negative Elongation Factors

Elongation Maintenance Factors

During transcription, RNA polymerase II is aided by specific factors as it encounters numerous blocks to elongation inherent in a template sequence. During normal transcription *in vivo*, each nucleotide addition to an RNA chain requires ~50 ms on average. However, *in vitro* RNA polymerase II may pause for seconds or minutes at specific sites in the absence of any accessory factors. TFIIF, a factor required for RNA polymerase II initiation, can also decrease the time that the polymerase spends at pause sites. This has the effect of increasing the overall elongation rate because, for the most part, the elongation rate is determined by how long the polymerase stops at the strongest pause sites. It has been hypothesized that the mechanism utilized by TFIIF involves an interaction-induced change in the polymerase from the paused conformation to the elongation competent form. Other factors that belong in this same class are eleven-nineteen lysine-rich leukemia and elongin, but TFIIF has the most dramatic elongation stimulatory activity. The elongation factor S-II functions by a completely different mechanism. At some sites a fraction of RNA polymerase II molecules fall into an arrested conformation from which they cannot escape unaided. At these sites the 3' end of the nascent transcript is removed from the active site of the polymerase as the polymerase backslides along the template while maintaining an RNA:DNA hybrid. When this happens, the polymerase may remain engaged for hours or days without extending the transcript. S-II stimulates an intrinsic ribonuclease activity of the polymerase that removes the unpaired 3' end of the transcript and puts the new 3' end in register with the active site of the polymerase. This reactivates elongation and the polymerase has a second chance to pass the arrest site. Eventually, all polymerases can pass the arrest site, although many may require several rounds of S-II-mediated transcript cleavage. Through the combined function of both classes of factors, the elongation rate of RNA polymerase II is maintained between 1000 and 1500 nucleotides per minute.

Figure 1 RNA polymerase II elongation control. After initiation, pol II enters abortive elongation by default because of the action of N-TEFs, such as DSIF and NELF. Phosphorylation of the CTD of the large subunit of RNA polymerase II by P-TEFb causes the transition into productive elongation. If P-TEFb does not act, transcription is prematurely terminated by TTF2.

Elongation Control

In addition to the factors that maintain efficient elongation, there is another set of factors responsible for regulating the efficiency of initiated polymerases to reach the 3' end of genes. This process has been termed 'RNA polymerase II elongation control' and is best viewed as an obligatory event mediated by the default action of negative factors, N-TEFs, and the regulated action of a positive factor, P-TEFb (Figure 1). The process was demonstrated *in vitro* by first showing that the transcription inhibitor DRB could block the production of long, but not short, transcripts. Elongation control was further characterized by the separation of N-TEFs, which direct polymerases to generate only short promoter proximal transcripts, from a positive factor, ultimately identified as P-TEFb, which reverses the action of the N-TEFs. A combination of the action of the N-TEFs and the activity of transcription termination factor 2 (TTF2) results in a process called 'abortive elongation' characterized by the premature termination of transcripts before the mature 3' end of the gene is reached. P-TEFb plays a key role in that it is responsible for the transition into productive elongation. Stated in another way, the ability to produce mRNAs is directly linked to the activity of P-TEFb. Elongation control machinery exists in all eukaryotic species that have been examined and the current evidence suggests that P-TEFb is required for transcription of most genes.

N-TEFs and Termination Factors

The evidence gathered so far points to the existence of two factors (DSIF and NELF) that play a negative role in elongation control. DSIF, the DRBIF, was discovered as a protein required for DRB sensitive transcription *in vitro*. It is comprised of two subunits with strong sequence similarity to the yeast proteins SPT4 and SPT5. DSIF has almost no function on RNA polymerase II alone. The NELF also has no effect on RNA polymerase II alone, but the combination of NELF and DSIF is able to slow the elongation rate and cause the polymerase to reside longer at pause sites. In this way, NELF and DSIF act in exactly the opposite way as TFIIF, which reduces pause time. NELF is comprised of four subunits, including a

putative RNA-binding protein called RD. A defined elongation control system comprised of isolated RNA polymerase II elongation complexes (NELF, DSIF, and P-TEFb) displays many of the properties of elongation control seen when transcription is carried out in nuclear extract. DSIF is involved in controlling transcription from the HSP70 locus in *Drosophila*, but the generality of its function has not been demonstrated. Although removal of DSIF in *Caenorhabditis elegans* using RNA interference techniques relieved most of the requirements of P-TEFb at a heat shock locus, similar results were not found in expression of several other genes. These facts along with the fact that homologs of NELF subunits have not been identified in many organisms suggest that other negative factors, which operate at a wide variety of genes, remain to be discovered.

So far only one transcription termination factor, TTF2 (formerly and uninformatively called factor 2), has been identified. It is a member of the SWI2/SNF2 family of proteins that are generally involved in disrupting protein nucleic acid interactions. It binds to both single- and double-strand (ds) DNA and has a strong dsDNA-dependent adenosine triphosphatase activity that is required for termination activity. The termination activity of TTF2 is inhibited by TFIIF, and while the mechanism of this inhibition is unknown, it provides a possible method to control the activity of TTF2 during transcription. The role of TTF2 seems to operate outside of the elongation control process in that its negative effect is not directly reversed by P-TEFb. However, a role for the factor in abortive elongation (premature termination) or in normal termination associated with mature 3' end formation has not been ruled out.

P-TEFb

Subunits and Activity

P-TEFb is a cyclin-dependent kinase comprised of Cdk9 and one of several cyclin subunits. Three genes in humans – T1, T2, and K – encode cyclin subunits that can associate with and activate Cdk9. Two cyclin T genes have been found in *C. elegans*, but only one in *Drosophila*. Supporting a broad role in gene expression, knockout of Cdk9 in *C. elegans* causes loss of gene expression and death at the same early stage as knockout of one of the subunits of RNA polymerase II. The same lethal phenotype is observed when both cyclin Ts are knocked out. The carboxyl terminal domain (CTD) of the large subunit of RNA polymerase II is phosphorylated by P-TEFb, and this domain has been shown to be required for the function of P-TEFb in the transition into productive elongation. The CTD is comprised of multiple repeats of the heptapeptide YSPTSPS, and P-TEFb predominately phosphorylates the second serine. P-TEFb had been shown to have broad substrate specificity *in vitro* and will phosphorylate the large subunit of both DSIF and TFIIF. Although the CTD is phosphorylated by P-TEFb and is required for the function of P-TEFb in transcription, there may be other important functional phosphorylation targets. The effect of DRB on transcription is explained by the fact that it inhibits the kinase activity of P-TEFb. All P-TEFb inhibitors reduce the production of mRNAs *in vivo* and are lethal at high concentrations. Flavopiridol, the most potent P-TEFb inhibitor found, is in clinical trials against cancer.

Recruitment of P-TEFb

P-TEFb interacts in a functional way with a number of important transcription factors. Cyclin T1 interacts with the HIV transactivator Tat, and P-TEFb containing cyclin T1 can be recruited to elongation complexes on the HIV template through the interaction of Tat and cyclin T1 with a stem-loop structure that forms in the nascent HIV transcript called 'transactivation response (TAR)'. This recruitment of P-TEFb activates transcription of the HIV genome. A cellular factor, CIITA, which is involved in activating transcription of the major histocompatibility complex (MHC) class II genes, has also been shown to function through interaction with P-TEFb. That interaction is blocked in the presence of Tat suggesting that the binding site is similar for the viral and cellular protein and providing a mechanism for inhibition of MHC class II gene expression during HIV infection. Other transcription factors and enhancer binding proteins – including nuclear factor kappa B, c-myc, major Cdk9-interacting elongation factor, and the androgen receptor – have been demonstrated to various degrees to have functional interactions with P-TEFb.

Recruitment of P-TEFb through artificial targeting to promoter DNA or to nascent RNA has revealed several important aspects of its function. First, when a protein is expressed in which Cdk9 or cyclin T1 or T2 is tethered to the DNA-binding domain of a yeast protein (Gal4) and the binding sites for that protein are placed close to a human promoter, transcription is stimulated from that promoter. Besides the core promoter elements, SP1 binding sites are also required to see an effect of the recruited P-TEFb in this system. This is consistent with the model for P-TEFb function because P-TEFb only affects polymerases that have already initiated, and SP1 increases the initiation efficiency. Expression of Cdk9, cyclin T1, T2, or K tethered to an RNA-binding domain (e.g., HIV rev) activates transcription of a gene containing the appropriate RNA element. In both tethering experiments, the untethered component of P-TEFb is also recruited due to the inherent interaction between P-TEFb subunits. Cyclin K does not work when tethered to DNA elements because it lacks a CTD present on both cyclin T1 and T2 that plays another role by interacting with the CTD of the large subunit of RNA polymerase II.

Control of P-TEFb by 7SK

Very recently, the laboratories of Olivier Bensaude and Qiang Zhou simultaneously discovered the small cellular RNA, 7SK, in association with a fraction of P-TEFb in cells. The large complex containing P-TEFb and 7SK was relatively inactive compared to the free P-TEFb (**Figure 2**). Addition of small amounts of compounds that inhibit elongation by RNA polymerase II causes a reduction in the large form of P-TEFb *in vivo* and a concomitant increase in the small active form. Evidently, a cell will try to compensate for reduced production of mRNAs by activating more P-TEFb. The change in large to small form of P-TEFb can occur within minutes and is reversible. The significance of the large form of P-TEFb was demonstrated using a mouse model of cardiac hypertrophy. Heart cells that were stimulated to grow in size had an increase in P-TEFb activity, but no increase in the amount of P-TEFb. It was shown that all hypertrophic signals tested caused a release of 7SK. The signal transduction pathways involved in hypertrophy of cardiac cells at least partially routes through the elongation control pathway.

Figure 2 Control of P-TEFb by 7SK. The amount of P-TEFb activity in the cell can be quickly adjusted by the reversible association of 7SK RNA. The large form with 7SK bound is inactive.

Integration of Elongation Control and Gene Expression

Elongation control may play a very significant role in controlling eukaryotic gene expression. Most RNA polymerase II molecules found transcribing human genes require the prior function of P-TEFb. Recruitment of P-TEFb by transcription factors allows specific genes to be targeted, and both the targeted and the untargeted functions of P-TEFb may allow global regulation of mRNA production. Regulating the conversion of the large to small P-TEFb form by signal transduction pathways is another global means to regulate mRNA levels. Overall, the combined action of negative and then positive factors results in a kinetic delay of the progression of polymerases down the gene. This may provide a window of opportunity for RNA-processing machinery to function or associate with the elongating polymerase, ensuring a truly productive elongation event resulting in a complete, functional mRNA. The human capping enzyme is functionally coupled to transcription and guanylates the nascent transcript before P-TEFb acts. However, some components of the polyadenylation and splicing machinery have been shown to associate with the phosphorylated CTD. Perhaps the processing machinery is functionally coupled to transcription through interactions provided by elongation control and scans the nascent transcript for processing sites as it is being made. Many mechanistic details of how RNA polymerase II elongation control is accomplished and the ramifications of the process on subsequent events remain to be determined.

Glossary

Abortive initiation The process during transcription initiation in which RNA polymerase makes and releases short RNA transcripts. As the RNA transcripts clash with the $\sigma 3.2$ -loop near the active site, the short RNA transcripts are released, and the process begins again.

Closed complex For transcription of genes, RNA polymerase is recruited to the promoter DNA to form the initial RNA polymerase and DNA complex. In this form, DNA is entirely double stranded.

Holoenzyme The complete multisubunit RNA polymerase including catalytic core enzyme and promoter DNA recognition σ factor.

Open complex The transcription-ready state complex, which is generated by a significant conformational

change of the closed complex which includes melting of promoter DNA.

Promoter A DNA sequence that initially binds to RNA polymerase and is the site at which the closed complex is formed and subsequently isomerizes to the open complex for transcript initiation.

Secondary channel The channel in RNA polymerase that is the path of substrate NTPs or backtracked RNA.

Trigger loop The loop that recognizes the correct NTP substrate at the active site of RNA polymerase.

It changes its conformation from a disordered loop to two α helices when the correct NTP enters the active site and triggers phosphodiester bond formation.

Transcription: Basic Mechanism

For transcribing RNA based on the DNA sequence, RNAP unwinds a small region of double-stranded DNA (~ 10 nucleotide residues) to the single-stranded form and synthesizes RNA as a complementary sequence of the DNA template (Figures 1 and 2(b)). The unwound region of DNA is called the transcription bubble that contains a DNA–RNA hybrid of ~ 8 base pairs. For synthesis of RNA, nucleotide substrate and catalytically essential divalent cations in addition to the single-stranded template DNA must be accommodated at the RNAP active site. One of four ribonucleotide triphosphates – ATP, GTP, CTP, and UTP – forms a Watson–Crick base pair with a DNA template base and its α -phosphate group is attached by a 3'-hydroxyl of the growing end of the RNA. As a result, a linear RNA is built in the 5' to 3' direction.

For the nucleotidyl transfer reaction (transcription), a two metal-ion catalytic mechanism has been proposed (Figure 2(b)), as the enzyme possesses two divalent catalytic and nucleotide-binding metal cations (Mg^{2+} or Mn^{2+}) chelated by three Asp residues in the absolutely conserved NAEFDGD motif found in all cellular RNAPs. The catalytic metal (Mg^{2+} I in Figure 2(b)) is a Lewis acid, coordinating the RNA 3'-OH lowering its pK_a and facilitating the formation of attacking oxyanion. The nucleotide-binding metal (Mg^{2+} II in Figure 2(b)) is coordinated by the triphosphate of the incoming nucleotide and stabilizes a pentacovalent phosphate intermediate during the nucleotidyl transfer reaction. Both metal ions are proposed to have octahedral coordination at physiological Mg^{2+} concentrations. In bacterial RNAP, the catalytic metal has a higher affinity to the active site and is coordinated at the active site even in the absence of DNA template or substrates. By contrast, the nucleotide-binding metal has a lower affinity and is only present with a nucleotide substrate at physiological Mg^{2+} concentration.

The nucleotide addition is accomplished through the formation of a phosphodiester bond and release of pyrophosphate (PPi) as a by-product. The free energy for this reaction is rather small ($\Delta G = -3.5 \text{ kcal mol}^{-1}$), but additional free energy is provided *in vivo* by rapidly hydrolyzing PPi into two phosphate groups by enzyme pyrophosphatase that makes the entire reaction highly energetically favorable ($\Delta G = -7 \text{ kcal mol}^{-1}$) under physiological condition, which is practically irreversible.

All cellular organisms including bacteria use multisubunit DNA-dependent RNAP for transcribing most of the RNAs in cells. In bacteria, well-characterized RNAPs are from the Gram-negative bacterium *Escherichia coli* and the Gram-positive bacterium *Bacillus subtilis*. For structural studies, RNAPs isolated from the thermophilic bacteria, *Thermus aquaticus* and *Thermoplasma thermophilus*, have been used for X-ray crystallography, but *Thermus* RNAPs are distantly related to *E. coli* and *B. subtilis* RNAPs and also to RNAPs from pathogenic bacteria species.

Transcription Cycle: Initiation

The catalytically competent bacterial core RNAP (subunit composition $\alpha_2\beta\beta'\omega$, with a molecular mass of $\sim 400 \text{ kDa}$) is evolutionarily conserved in sequence, structure, and function from bacteria to humans. The core RNAP subunits are encoded by *rpoA* (for α subunit, MW: 36 kDa), *rpoB* (for β subunit, MW: 150 kDa), *rpoC* (for β' subunit, MW: 155 kDa), and *rpoZ* (for ω subunit, MW: 10 kDa) genes. The overall shape of core RNAP resembles a crab claw. The β and β' subunits form each claw arm, generating a cleft for double-stranded DNA binding. The enzyme active site is located at the bottom of the cleft that coordinates catalytic Mg^{2+} . The architecture around the cleft including the active site is highly conserved among all cellular RNAPs, which indicates that the catalytic mechanism

Figure 1 The transcription cycle. RNAP core enzyme (α , light brown; β , cyan; β' , pink; ω , white), σ factor (orange), DNA (template strand, dark green; nontemplate strand, light green; -10 and -35 elements, yellow), and RNA transcript (red) at different stages of the transcription cycle. Transcript elongation factors NusA and NusG, ribosome (30 S, yellow; 50 S, gray) and transcription termination factor ρ are also shown and labeled. From the open complex to transcription termination, β is removed and the outline of β is shown as a cyan line to reveal the inside of RNAP. All structures in this figure are X-ray/NMR structures of *E. coli* proteins or homology models of *E. coli* proteins based on structures from *T. aquaticus*.

Figure 2 Bacterial RNA polymerase active site and mechanism of catalysis. (a) Active site structure of the bacterial RNA polymerase (PDB: 205J). Template DNA (green), nontemplate DNA (light green), RNA (red), bridge helix (blue), trigger loop (orange), Mg^{2+} ions (yellow), and incoming NTP at N-site (stick model). (b) Mechanism for two- Mg^{2+} -mediated catalysis of nucleotidyl transfer reaction. Two substrates of the active site, P- and N-sites, are shown. NTP is shown in green. The red arrows illustrate the nucleophilic attack of the RNA 3' oxyanion on the NTP α -phosphate and the reaction involves stabilization of a trigonal-bipyramidal transition state by two Mg^{2+} ions.

of RNA synthesis from bacteria to humans is conserved. Although the two largest subunits, β and β' , provide most of the catalytic functions, their assembly is dependent on the presence of two α subunits, which form a platform for assembly.

The core enzyme carries out highly efficient RNA transcription using DNA as a template; however, transcript initiation from specific DNA sequences, called 'promoters', requires an additional DNA sequence recognition protein, σ factor, which binds the core RNAP to form the holoenzyme (Figure 1).

The σ factor transiently associates with the core enzyme for promoter recognition and it dissociates from the core enzyme once the RNAP starts processive transcript elongation. Bacteria encode multiple σ factors (seven in *E. coli*) and the most common *E. coli* σ factor is σ^{70} (encoded by *rpoD* gene) that carries out transcription of housekeeping genes. Other σ factors can substitute housekeeping σ under certain growth and stress conditions and direct RNAP to alternative sets of promoters for optimizing gene expression for adaptation and for cell differentiation such as sporulation in *B. subtilis*.

Most bacterial σ factors belong to a homologous family closely related to *E. coli* σ^{70} , with distinct regions of highly conserved sequence. Group 1 (or primary) σ s, SigA, direct the majority of transcription during log-phase growth. Structural analysis reveals that group 1 σ s are comprised of four flexibly linked domains, $\sigma 1.1$, $\sigma 2$, $\sigma 3$, and $\sigma 4$, containing conserved regions 1.1, 1.2–2.4, 3.0–3.1, and 4.1–4.2, respectively.

In the holoenzyme, the globular domains of σ lay spread out across the upstream face of the RNAP crab claw. The promoter-binding determinants of σ factor, $\sigma 2$ (–10 element) and $\sigma 4$ (–35 element), are solvent exposed, spaced according to their cognate DNA elements. The $\sigma 3$ and $\sigma 4$ domains are separated by 45 Å in the holoenzyme. This distance is spanned by an extended 33-residue linker, comprised primarily of σ region 3.2 (the $\sigma 3.2$ -loop), which loops into the RNAP active site channel, then winds its way out through the RNA exit channel.

The σ and core RNAP interaction is very stable, with a dissociation constant estimated to be $\sim 10^{-9}$ M. Each of the σ domains, as well as the linkers connecting them, interacts with the core RNAP. Nevertheless, when RNAP enters the elongation phase of transcription, σ is generally released. These seemingly contradictory properties are explained by the σ architecture. The simultaneous, independent binding of discrete structural elements of σ ($\sigma 1.1$, $\sigma 2$, $\sigma 3$, $\sigma 3.2$ -loop, and $\sigma 4$) to different parts of the core provide for high-affinity binding, without any one σ -domain/core interaction being particularly stable. Stepwise structural transitions during initiation could induce the dissociation of individual σ -domains, one by one, effecting eventual σ release.

The search for a promoter in the genome occurs through occasional collision and/or sliding of RNAP along DNA. Sliding greatly accelerates the search, which is concluded by establishment of specific contacts between RNAP and a promoter in a relatively unstable closed complex (Figure 1). The RNAP holoenzyme binds to the promoter DNA region from –60 to +20 nucleotides relative to the transcription start site and the σ factor recognizes two 6 bases DNA sequences centered on the positions around –35 and –10 (called the –35 and –10 elements). The consensus sequences of the –35 and –10 elements are conserved in bacteria and their sequences are TTGACA and TATAAT, respectively.

RNAP unwinds DNA from the –10 element downstream past the transcription start site (+1) to form the transcription bubble. Only the single-stranded template strand is directed to the active site and the double-stranded downstream DNA from +5 to roughly +12 is clamped by the RNAP DNA-binding cleft to form the open complex (Figure 1).

Upon formation of the open complex, the RNAP active site takes NTP substrates through the secondary channel and

starts synthesizing RNA. While DNA polymerase requires a DNA or RNA primer for starting DNA synthesis, RNAP is able to initiate RNA synthesis from NTPs in a process called primer-independent or *de novo* transcript initiation. Transcript initiation is the only step in the entire transcription process where two nucleotide substrates are loaded at the active site followed by a nucleotidyl transfer reaction. A short transcript only a few nucleotides in length encounters a $\sigma 3.2$ -loop in its exit path that dissociates RNAs from the active site; this cycle continues several times (abortive initiation). At each cycle, the elongating RNA displaces the $\sigma 3.2$ -loop out of its path. Eventually, the RNA chain that elongates to a length of around 12 nucleotides fills completely the DNA/RNA hybrid and the upstream RNA exit channel under the β subunit flap and thereby displaces σ from its path and ends the abortive initiation.

The displacement of the $\sigma 3.2$ -loop couples the presence of an ~ 12 -nt RNA chain to the initial stages of promoter escape by destabilizing $\sigma 4/\beta$ flap interactions. Release of $\sigma 4$ from the β flap would destabilize the $\sigma 4$ –35 element interactions that allow the RNAP to escape from the promoter and translocate downstream on the DNA for RNA elongation. This transition into RNA elongation does not require the complete release of σ , since other domains of σ bound to RNAP are not incompatible with the paths of the DNA and RNA in the elongation complex (EC). Eventually, complete release of σ results in the EC with core RNAP (Figure 1). In some cases, however, σ remains associated with RNAP in the early, middle, or late stages of transcript elongation, and the timing of σ release is a stochastic process.

Transcription Cycle: Elongation

During transcript elongation, the elongation factors NusA and NusG associate with the EC (Figure 1) and regulate the velocity of RNA synthesis, transcriptional pausing, and termination efficiency. NusA is a multidomain protein with a rod-shaped structure. The NusA N-terminal domain associates with the β flap of RNAP while the C-terminal region contains several RNA-binding motifs and also binds with the α subunit C-terminal domain of RNAP. NusA enhances intrinsic termination as well as transcriptional pausing by interacting with nascent RNA hairpins.

NusG consists of the NusG amino-terminal (NGN) domain and Kyprides–Onzonis–Woese (KOW) motif at the C-terminal domain (hence also called KOW domain), and these two domains fold independently and are connected by a flexible linker. The NGN domain associates with the β' subunit coiled-coil motif of RNAP and regulates the velocity and processivity of the transcript elongation. The NusG–KOW domain plays important roles in interacting with other proteins, for example, it contacts the elongation factor NusE, which is also the ribosomal S10 subunit. This interaction may play an important role in the coupling of transcription and translation. During the transcription of protein-coding genes, the EC is followed by a ribosome (Figure 1) and the overall transcript elongation rate is tightly controlled by the rate of protein translation. This transcription and translation coupling prevents RNAP backtracking and facilitates readthrough of roadblocks on the

DNA template. Both NusA and NusG are essential components of anti-termination complexes for the ribosomal RNA (*rnm*) and phage λ operons, and participate in ρ -dependent transcription termination.

Transcription Cycle: Termination

Transcription termination is the final step of gene expression, which plays an important role in making an end of RNA without affecting unnecessary gene expression from downstream genes. This is particularly important for the 'gene rich' genome of bacteria. There are two types of termination: ρ -dependent termination and ρ -independent intrinsic termination. The ρ -dependent termination requires a hexameric helicase protein ρ , which loads onto nascent RNA strands at *rut* (rho utilization) sites (Figure 1) followed by stimulating an RNA-dependent adenosine triphosphatase (ATPase) activity. Coupling of ATP hydrolysis translocates ρ in the 5' $\rightarrow$ 3' direction along the RNA toward the EC. Eventually, ρ bumps into the RNAP and pulls out RNA from the EC, causing the release of the transcript and dissociation of RNAP from DNA.

The intrinsic terminators contain short self-complementary GC-rich sequences followed by an oligo-A tract on the template DNA sequence. Transcription of such sequences is accompanied by pausing of RNAP due to backtracking, which ensures the formation of a hairpin-like RNA structure. The RNA hairpin destroys the nucleic acid contacts with RNAP, which leads to collapse of the transcription bubble and disintegration of the EC.

Nucleotide Additional Cycle and Proofreading

Bacterial RNAP forms a stable EC with DNA and RNA for processive RNA extension of up to $\sim 10^4$ bases with a rate of 50–100 nucleotides s^{-1} . During transcript elongation, the EC constantly unwinds the double-stranded downstream DNA before the template DNA strand enters the active site. The single-stranded template DNA within the transcription bubble (12–14 bases in length) is positioned at the active site and forms an ~ 8 -nucleotide hybrid with nascent RNA. The template DNA is rewound with the nontemplate DNA strand at the end of the transcription bubble to form the double-stranded upstream DNA.

The RNAP active site, which is buried within a cleft between the β and β' subunits, is connected with the outside through three channels (main, secondary, and RNA exit) to synthesize RNA efficiently. To extend RNA, RNAP moves the 3'-end of RNA to the P-site (primer or product site, which is also referred to as the i site, Figure 2(a)) to make a space for the incoming nucleotide, which is accommodated at the insertion site (N-site, also referred to as the $i + 1$ site) for the nucleotidyl transfer reaction. Downstream DNA is accommodated at the cleft of the main channel and maintains its duplex DNA structure until the $i + 2$ position. The β subunit fork loop 2 plays a role in DNA strand separation as Arg side chain stacks on the $i + 2$ base pair and blocks the passage of the duplex DNA towards the $i + 1$ site (Figure 2(a)). The template DNA strand

forms a sharp kink between the $i + 1$ and $i + 2$ sites to present only one single-stranded DNA base at the $i + 1$ site for each round of the nucleotide addition cycle. The 3'-end of the RNA positions near the catalytic metal and also above a funnel-like secondary channel, which is an entry pore of nucleotide substrates to the active site and 3'-end RNA exit site when RNAP backtracks for transcriptional proofreading. The 5'-end of RNA positions at the RNA exit channel, which is below the β flap domain.

The three protein loops, the lid, the rudder, and the β switch 3, form an interaction network with the upstream edge of the DNA/RNA hybrid (Figure 2(a)). The lid stacks on the upstream base pair and sterically blocks growth of the hybrid in order for RNA to separate from the template DNA. The rudder interacts with DNA separated from the hybrid preventing re-association with the RNA. The β switch 3 interacts with the first displaced RNA base presumably to help the separation of RNA from the hybrid and the re-annealing of the template and nontemplate DNA strands.

RNAP has to operate high-fidelity transcription since transcription errors could produce nonfunctional ribosomes, transfer RNAs (tRNAs), or messenger RNAs (mRNAs) that produce mutant proteins without proper functions. Transcriptional accuracy of bacterial RNAP is relatively high with an estimated error rate of less than 10^{-5} . RNAP secures transcriptional fidelity by using two strategies, substrate selection and proofreading, which remove a mismatched nucleotide from nascent RNA by RNA cleavage activity. RNAP carries out this RNA cleavage reaction by using the same tunable active site that also carries out RNA extension.

To select the correct NTP substrate, RNAP discriminates (1) NTPs from deoxyNTPs (dNTPs) and (2) correct NTPs from incorrect NTPs. To discriminate NTPs from dNTPs, RNAP recognizes the 2'-OH group of the ribose by hydrogen bonding with a side chain of an Asn residue found in the NADFDGD motif (Figure 2(a)). Mutation of this Asn residue increases dNTP incorporation. To discriminate correct NTPs from incorrect NTPs, RNAP carries out two-step reactions that involve an isomerization of the RNAP active site. In the first step, NTP binds to a pre-insertion site for testing Watson–Crick base pairing with the DNA template. Once the Watson–Crick base pairing is established, the NTP is delivered to the insertion site (N-site) by conformational changes of the trigger loop and bridge helix that lead to alignment of the reactive groups including the 3'-OH group of RNA and the triphosphate group of the NTP for the nucleotidyl transfer reaction (Figure 2(a)).

The trigger loop changes its conformation depending on the presence or absence of NTP at the active site, and also correct and incorrect nucleotide at the active site. Without NTP or with an incorrect NTP at the active site, the trigger loop is located farther than 30 Å away from the insertion site. By contrast, with a correct NTP at the insertion site, the trigger loop refolds its structure to form the two α -helices with extensive interactions with the nearby bridge helix and positions in proximity to the insertion site (Figure 2(a)). In this trigger loop conformation, it interacts with all parts of the nucleotide for the alignment of reactive groups for catalysis.

Bacterial RNAP is one of the strongest motor proteins, which converts energy associated with the nucleotidyl transfer reaction into mechanical motion along the DNA template.

Each nucleotide addition cycle couples with the translocation of the DNA/RNA hybrid at the active site that moves a freshly made 3'-end of RNA from the N- to the P-sites for making an empty N-site and brings an unpaired DNA base to the $i + 1$ position for the next round of the nucleotide addition. In the case of cellular RNAPs including bacterial RNAP, the Brownian Ratchet model was proposed for a mechanism of translocation. In this model, the 3'-end of RNA changes its position between pre- and post-translocated states at a speed more rapid than that of nucleotide loading, and the loading of a nucleotide at the N-site drives the RNAP movement for the forward translocation.

When RNAP incorporates a mismatched base in RNA, it slows down and pauses transcript elongation and eventually backtracks RNA to form a frayed RNA 3'-terminal nucleotide. RNAP uses the RNA hydrolysis activity either by an intrinsic or by a Gre factor stimulated RNA cleavage activities for removing one or a few nucleotides of RNA containing a misincorporated nucleotide. This RNA hydrolysis also makes a fresh 3'-OH group at the end of RNA to restart transcript elongation. Gre stimulates RNA hydrolysis activity of RNAP by more than 3000-fold and accesses the RNAP active site through the secondary channel, placing Asp/Glu residues at the RNAP active site for chelating Mg^{2+} for the RNA hydrolytic reaction. Bacterial RNAP has another RNA cleavage activity, which is just reversing the RNA synthesis reaction in the presence of PPi to release NTP from the 3'-end of RNA. This reverse reaction is known as 'pyrophosphorolysis'. For this reaction, the RNA 3'-end has to be positioned at the N-site (pretranslocated register) and RNAP is able to progressively shorten the RNA. The RNAP pyrophosphorolysis reaction requires a higher concentration of PPi that cannot be achieved in physiological conditions and

also nucleotide concentrations in cells are preferential for the RNA synthesis reaction; thus, RNAP cannot use the pyrophospholysis reaction for proofreading *in vivo*.

Transcription Inhibitions by Antibiotics

Transcription is an essential process in bacteria and, as such, is a target for antimicrobial drugs (antibiotics). Bacterial RNAP is an excellent target for antibiotics because (1) it is an essential enzyme for transcription, (2) the bacterial RNAP sequences are highly conserved, allowing for antibiotics to be effective against a wide range of species, and (3) the bacterial RNAP sequences are less conserved with the eukaryotic RNAP sequences, allowing for therapeutic selectivity. In addition, bacterial RNAP is a large enzyme composed of many subunits that increases the likelihood of finding new effective antibiotics.

There are four well-characterized antibiotics, Rifampicin (Rif), Sorangicin (Sor), Streptolydigin (Stl), and Myxopyronin (Myx), which work against bacterial RNAP. Biochemical, genetic, and crystallographic studies of RNAP-antibiotic complexes identified three separate target sites (Rif/Sor, Stl, and Myx sites, Figure 3) and three different mechanisms for inhibiting bacterial RNAP.

One of the best-characterized antibiotics against RNAP is Rifampicin (Rif), which is a member of the Rifamycin family of antibiotics, active against a broad range of Gram-positive and Gram-negative bacterial infections, and in clinical use in the treatment of tuberculosis. The crystal structure of the *T. aquaticus* core RNAP-Rif complex identified the Rif-binding site on the β subunit adjacent to the RNAP active site (Figure 3 (a)), which is not overlapping with the DNA binding or catalytic center

Figure 3 Targets of small-molecule inhibitors of RNAP. (a) Target of rifamycins (Rif). (b) Target of sorangicin (Sor). (c) Target of streptolydigin (Stl). (d) Target of myxopyronin (Myx). Each panel shows two orthogonal views of RNAP. Red, sites of substitutions conferring resistance to the specified inhibitor; blue, sites of substitutions conferring resistance to rifamycins; violet sphere, active-center Mg^{2+} . but overlaps with the path of nascent RNA. The structure proposed the steric clash model, which is consistent with biochemical observations that Rif inhibits transcript initiation and extension, but does not inhibit elongating RNAP that already has a longer RNA. The Rif-binding site of RNAP is also a binding site for another RNAP inhibitor Sorangicin (Sor) (**Figure 3(b)**), which is a polyketide-derived macrocyclic-polyether product from *Myxobacterium Sorangium cellulosum*. As found for Rif, Sor inhibits transcript initiation by preventing the extension of short RNA (2 ~ 4 nt length). Because of the proximity of their binding sites on RNAP, Rif and Sor show partial cross-resistance; some Rif-resistant mutants are resistant to Sor, and all Sor-resistant mutants are resistant to Rif.

Streptolydigin (Stl) is a polyketide-derived tetramic-acid antibiotic produced by the Actinomycete *Streptomyces griseoflavus*. Stl binds to key elements of the RNAP active site for transcription – the bridge helix and the trigger loop (**Figure 3(c)**) – and inhibits all reactions of RNAP transcription by blocking conformational changes of these elements that occur during transcription. Crystal structures of the RNAP–Stl complexes revealed that the Stl traps the bridge helix and trigger loop in straight and unfolded conformational states, respectively, by direct interactions with these elements. Because the Stl target site is not overlapping with the Rif/Sor target site (**Figures 3(a)** and **3(b)**), Rif and Stl exhibit only minimal cross-resistance.

Myxopyronin (Myx) is a polyketide-derived a-pyrone antibiotic produced by the *Myxobacterium Myxococcus fulvus* Mxf50. Myx binds the RNAP switch region (**Figure 3(d)**), which is a hinge of the RNAP clamp for opening and closing of the DNA-binding channel. Upon binding, Myx inhibits transcript initiation by preventing formation of the promoter open complex. Crystal structures of the RNAP–Myx complexes with biochemical studies proposed two models of inhibition that include the following: Myx inhibits transcription (1) by preventing opening of the RNAP clamp to permit entry and unwinding of DNA (hinge jamming mechanism) or (2) by interfering with interactions between RNAP and the unwound DNA template strand. Because the Myx target site is away from the Rif/Sor target site (**Figures 3(a)** and **3(b)**), Rif and Myx exhibit absolutely no cross-resistance.

Although much work has been completed regarding antibiotics that act by inhibiting RNAP transcription, the escalating problem of antibiotic resistance necessitates further research. The increasing prevalence of bacterial strains resistant to the Rifamycins is making treatment of tuberculosis more difficult. Bacteria are developing various resistance strains by point

mutations in the genes encoding RNAP subunits. This increasing and dangerous problem calls for further research into the modification of existing RNAP-acting drugs as well as the development of novel antibiotics that utilize different methods of inhibiting RNAP.

Introduction

Enzymatic Activities of RNA Polymerase

In enzymological terms, RNA polymerase (RNAP) belongs to a nucleotidyl transferase class of enzymes. During RNA polymerization (forward reaction), it catalyzes (in a DNA-template dependent manner) the transfer of ribonucleoside monophosphate moiety from ribonucleotide triphosphate (rNTP) to the 3'-terminal hydroxyl group of the growing chain of RNA product, producing pyrophosphate (diphosphate, PPi) as by-product. In a reverse reaction, pyrophosphorolysis, RNAP transfers ribonucleoside monophosphate moiety from the 3'-terminal nucleotide of RNA back to pyrophosphate resulting in degradation of RNA and formation of rNTPs. In addition, RNAP catalyzes RNase-like hydrolysis of nascent RNA acting as 3'-exoribonuclease and endoribonuclease. In the course of these reactions, RNAP produces shortened nascent RNA with the free 3'-hydroxyl group and ribonucleoside-5'-monophosphate (rNMP) or 2–19-nt-long oligoribonucleotide fragments with 5'-monophosphate, respectively. RNAP also possesses a DNA-helicase activity: it unwinds the double-stranded DNA (dsDNA), separates the DNA strands (DNA melting), and induces both positive and negative DNA supercoiling. Finally, RNAP is a DNA-translocase which acts as a powerful molecular motor. During transcription, it utilizes the energy released from rNTP binding and incorporation into the growing chain of RNA to generate substantial mechanical force and to move unidirectionally along the DNA template. All enzymatic activities of RNAP require the presence of two Mg^{2+} ions (one high-affinity and another low-affinity) at the catalytic center.

Subunit Composition

In bacteria, such as *Escherichia coli* (*Eco*), the catalytically active core enzyme consists of five subunits ($\alpha_2\beta\beta'\omega$): two α (~36 kDa), β (~150 kDa), β' (~155 kDa), and ω (~8.5 kDa), with the total molecular weight of ~380 kDa. On its own, the core enzyme is unable to recognize specific promoter DNA sequences, or melt the DNA and initiate transcription. To carry out these functions, it must bind one of several specificity factors, σ (or σ subunit, 20–70 kDa) to form RNAP holoenzyme ($\alpha_2\beta\beta'\omega\sigma$). Alternative σ factors bind competitively to the core, generating multiple forms of holoenzyme that can utilize different classes of promoters under various growth conditions and in response to stress. The number of σ factors in different bacterial species varies from one in *Mycoplasma genitalie* to seven in *Eco* to 60 in *Streptomyces coelicolor*. Besides σ , other regulatory transcription factors can bind RNAP to modulate its ability to recognize and bind promoters, modify its enzymatic activity, alter the rate of RNA synthesis and its processivity, and control the release of RNA product.

Transcription Cycle

Transcription process can be roughly divided into three major stages: initiation, elongation, and termination. At each of these steps RNAP is targeted by large number of regulatory factors. Initiation is the first and most complex step in transcription. During initiation, the σ^{70} -holoenzyme slides along the DNA scanning for the presence of two conserved hexamer elements of the promoter centered at positions –35 and –10 (with consensus sequences $^{-35}TTGACA^{-30}$ and $^{-12}TATAAT^{-7}$, respectively, relative to the transcription +1 start site) and separated by a $\sim 17 \pm 1$ -bp spacer. In addition to the conserved hexamers (that may differ from consensus), other elements immediately upstream and downstream of the –10 element ($^{-14}TG^{-13}$ extended –10', –15' regions, and 'discriminator' (DSR)) and A/T-rich regions upstream of the –35 element ('UP-element' at –45; –65), all contribute to specific recognition by the σ^{70} holoenzyme. The holoenzyme specifically binds to these elements to form a closed promoter complex (RPC). After several transitional steps the enzyme unwinds the DNA duplex around the –10 region (between nt –12 and +2) creating a 12–14-nt-long transcription bubble, and forms an open promoter complex (RPO). In the presence of rNTPs, RPO transforms into an initiating complex (RPinit) which forms the first phosphodiester bond between rNTPs positioned at +1 and +2 sites and the RNA synthesis commences. At this stage, RNAP exists in the form of a scrunched complex where the upstream DNA–RNAP contacts remain intact; the downstream DNA (from +1 to +15) is pulled into the enzyme and transcribed into the RNA, while the transcription bubble expands extruding the excess of ssDNA strands outside of the complex. The RPinit may proceed into either abortive or productive pathways. In the former, the enzyme enters the cycle of abortive initiation when it repetitively synthesizes and releases short RNAs without leaving the promoter. In the latter, the enzyme synthesizes RNA till it reaches a critical length (typically 11–15 nt), of which 8–9 nt are base-paired with the DNA template strand (DNA–RNA hybrid) and 2–6 nt are threaded through the RNA exit channel, escapes from promoter, and enters the elongation stage of transcription. This transition leads simultaneously to the loss of RNAP–promoter DNA contacts, σ dissociation, and formation of a highly stable and processive ternary elongation complex (EC).

Throughout elongation stage, the size of transcription bubble in EC remains constant at $\sim 12 \pm 1$ nt, and the size of RNA/DNA hybrid is maintained at 8–9 bp. EC can transcribe DNA over long distances (>10 000 bp) without dissociation and release of RNA product. However, the monotonous forward movement of EC can be interrupted by pauses which occur through at least two pathways. The first (type I) is induced by RNAP interaction with the nascent RNA secondary structures (such as RNA hairpins). This leads to distortion in RNA/DNA hybrid and temporary disengagement of RNA

3'-end from the active site. The second (type II) results from various roadblocks to RNAP translocation caused by DNA-binding proteins, misincorporated substrates, DNA lesions, and certain DNA sequences. During type II pausing, RNAP may slide back by 2–20 nt relative to the RNA 3' end (back-track). This results in extrusion of RNA 3'-terminus through the secondary channel of RNAP (see below) and concomitant repositioning of the catalytic center from the 3'-end to an internal site in RNA. Both types of pausing play important regulatory roles in transcription and in synchronization of transcription and translation. Under certain conditions, pausing could also lead to transcription arrest or dissociation of EC.

Transcription termination occurs when EC encounters a termination signal – a 20–35-nt-long G/C-rich RNA sequence of dyad symmetry that forms stem-loop structure immediately followed by a 7–9-nt-long stretch of Us. During termination, RNAP releases the nascent transcript and dissociates from the DNA template, after which it can rebind σ factor and start a new round of transcription. Under certain conditions, transcription termination can also be induced by termination factors ρ and Mfd.

Structure of RNAP Core Enzyme

Eco RNAP is the best characterized bacterial enzyme; however, its structure – determined by cryo-electron microscopy – has a

relatively low resolution of ~ 15 Å. The medium- and high-resolution structures of bacterial RNAP have been obtained by X-ray crystallography using thermophilic organisms *Thermus aquaticus* (*Taq*) and *Thermus thermophilus* (*Tth*). These include: the structures of *Taq* core (3.3-Å resolution); *Taq* holoenzyme (4 Å); *Tth* holoenzyme (2.6 Å); *Taq* and *Tth* RNAP complexes with several small molecule inhibitors and antibiotics (2.6–3.5 Å); the binary complex of *Taq* holoenzyme with promoter DNA fragment (6.5 Å); and the EC of *Tth* core with synthetic DNA/RNA scaffold (2.5 Å). In addition, high-resolution structures (1.8–2.9 Å) of individual domains of *Esc* RNAP subunits β' , α and σ , and their complexes with DNA and regulatory transcription factors were also reported. Together with information gained from a wide range of biochemical, biophysical, and genetic studies, these data refine our understanding of bacterial RNAP structure–function and provide a comprehensive view of transcription process and its regulation.

The structure of a typical bacterial RNAP, such as the *Taq*/*Tth* core enzyme, represents an asymmetric irregularly shaped ellipsoid with a deep cleft (internal channel) in the middle of the molecule, resembling a crab's claw. The overall dimension is about 155 Å in length (from the back to the tip of the claw), 115 Å in height (from the top to the bottom pincer), and 110 Å in width (alongside the channel). The top pincer of the claw is made up mostly of the β subunit, and the bottom pincer mostly of β' (Figure 1). The pincers are joined at the base of the claw by the N-terminal domains (NTDs) of asymmetrically

Figure 1 Structural overview of RNAP core. (a) Structure of *Taq* RNAP core shown in three rotational views, using Molsoft ICM Browser Pro program. Left panel, secondary channel view; middle panel, main channel view; right panel, RNA exit channel view. The structure is represented as lightly colored ribbons (α I, light gray; α II, olive; β , light yellow; β' , light cyan; ω , light blue) with structural elements emphasized in full color and indicated. Mg^{2+} ion is shown as small magenta sphere. The structures of β' -trigger loop, β' -rudder and β' N-terminal Zn-finger domains are modeled using the structure of *Tth* holoenzyme. The β' -NCD1 (G164-S449) and the α CTDs are not shown. (b) Secondary channel view of *Taq* RNAP core structure with β' -NCD1 colored blue. (c) Two rotational views of the modeled structure of *Eco* RNAP core (colored as above, except: β , light orange; β' , cyan; and nonconserved domains β SI1, β SI2, and β SI3 colored bright green, red and light yellow, respectively). Left panel, secondary channel view and right panel, main channel view.

placed α -dimer serving as a platform for RNAP assembly. α I-NTD binds only the β subunit, whereas α II-NTD binds mostly β' subunit. The ω subunit wraps around the β' C-terminus near the bottom pincer, serving as a β' chaperone.

RNAP Channels

The large internal space between the pincers is partitioned into three channels: the main channel (20–27 Å in diameter) and two minor channels (10–12 Å in diameter) that branch off from the primary channel to form the downstream-facing ‘secondary channel’ and the upstream-facing ‘RNA exit channel’.

The main (or primary) channel accommodates 13–15 bp of the downstream DNA duplex, 12–14 nt of the melted region of DNA (the transcription bubble), and up to 8–9 nt of DNA/RNA hybrid. In the holoenzyme, the main channel also accommodates the bulk of σ (domains σ 1– σ 3). The back wall of the primary channel – the most conserved part of the RNAP structure – contains a combination of β -sheet and α -helical elements of β and β' that comprise two juxtaposed six- β -stranded double- ψ β -barrel (DPBB) domains forming the active site cleft (see Table 1 for list of β/β' functionally relevant structural domains and elements). The DPBB domain of β' carries the catalytic loop with a triad of aspartates holding essential Mg^{2+} ions, whereas the DPBB domain of β harbors basic residues of the substrate-binding site (see below). The top and bottom walls of the channel are formed by β and β' clamps, respectively. The β clamp consists of an upstream-facing lobe-1 and a downstream-facing lobe-2 with two conserved loops, β fork-1 and β fork-2, protruding into the channel toward the active center. The downstream portion of the β' clamp is made of the C-terminal Zn-binding domain surrounded by groups of conserved α -helical elements that form the cradle for the downstream dsDNA. These include: two dsDNA-binding three-helix bundles, a long α -helical bridge (F-bridge or bridge helix) connecting the β and β' clamps near the active center and two adjacent α -helices of the flexible trigger loop (G-loop). Together with the four-strand β -sheet jaw domain, the trigger loop and bridge helix form the wall separating the primary and secondary channels (Table 1, Figures 1(a) and 1(b)). The upstream portion of the β' clamp consists of an extended N-terminal coiled-coil element (the major docking site for σ and elongation factors NusG and RfaH) with three bulging out loops: rudder, lid, and switch-2, all projecting into the main channel.

The secondary channel serves as an entry/exit pore for NTP substrates and by-products of RNA synthesis: the pyrophosphate, hydrolyzed 3'-terminal nucleotides (NMPs), and short oligoribonucleotides. It also provides an exit pathway for the backtracked RNA 3'-terminus and for abortive transcripts during initiation. The channel, which is made entirely of β' , has a funnel-like shape with wider opening on the outside surface of RNAP and a narrow opening near the catalytic center. This shape allows specialized secondary channel transcription factors to anchor at the entrance of the channel and reach through the channel to the RNAP active center to modulate its activity. The secondary channel's rim is made of the β' C-terminal coiled-coil element which serves as the major docking site for such factors as GreA, GreB, DksA, TraR, RNK, and Gfh1. The back wall of the channel consists of the extended loop adjacent

Table 1 Main structural elements of bacterial RNAP

Domains and structural elements	Residues (<i>T. thermophilus</i>)
β Subunit	
β DPBB domain	668–698; 832–879; 969–1004
β Clamp lobe-1 domain	18–142; 332–397

β' Secondary channel rim C-terminal coiled-coil	958–1015
β' Clip-1	1020–1035
β' Bridge (F) helix	1066–1103
β' C-terminal Zn-binding domain	1105–1116; 1155–1189
β' Clip-2	1353–1365
β' Trigger (G) loop	1233–1257
β' Jaw	1268–1330
β' Downstream clamp C-terminal HTL loop	1434–1444

to the bridge helix (F-loop), the helix-loop-helix (HLH) element clip-1 and a bundle of short α -helices connected by unstructured loops. The side wall is formed by the HLH element clip-2, the bridge helix, the trigger loop, and the jaw (Table 1, Figure 1).

The RNA exit channel has a curved shape which helps to accommodate the C-terminal domains of σ (σ 3–4 linker and σ 4) in the holoenzyme, and serves as an outlet for RNA product in ECs. The channel is also involved in RNA/DNA hybrid strand separation, and interactions with RNA hairpins in paused ECs and in transcription termination. The exit channel walls are mostly made of the upstream portions of β and β' pincers. The double-twisted loop switch-3 and the C-terminal HLH elements of β , together with the four-helix bundle just upstream of the main channel β -barrel of β' , comprise the back wall. The top wall consists of a flexible β flap domain,

whereas the bottom wall is made of the β' rudder, the lid, and the zipper elements (Table 1, Figure 1(c)). The outside rim of the channel is formed by the β flap tip helix, the β' N-terminal Zn-finger domain, and the β' exit channel rim helix. The C-terminal α -helical domain of α I, α I-CTD (connected to α I NTDs by flexible linker), may also contribute in forming the channel's rim.

Nonconserved Domains

Despite their overall similarity, bacterial RNAPs are structurally distinct, in part due to the presence of different large non-conserved regions residing in their β and β' subunits. These domains are dispensable for RNAP basic functions; however, they play important regulatory roles in transcription. For instance, the *Taq/Tth* RNAP contains a 283-residue domain in the nonconserved portion of β' present in the upstream β' clamp (*Taq/Tth* β' -NCD1). The crystal structure of this domain comprises five repeats of sandwich-barrel hybrid motifs (SBHMs) visible in *Tth* RNAP structure as an extended part of the lower β' pincer (Table 1, Figure 1(d)). The main function of β' -NCD1 is to stabilize core- σ 70 interactions (see below). Unlike *Taq/Tth*, the *Eco* β' has just one SBH motif which contributes to selective binding of alternative σ factors. Instead, *Eco* β' harbors a 188-residue insertion in the conserved G-loop (trigger) element (*Eco* domain β' -SI3), which is absent in *Taq/Tth* RNAP. The crystal structure of this flexible domain reveals two repeats of SBHM (Figure 1(e)) that can be modeled into the cryo-EM map of *Eco* RNAP–DNA promoter initiation complex (see Figure 3). *Eco* β' -SI3 is required for interaction with transcript cleavage factors GreA and GreB; it also strongly affects RNAP's intrinsic nucleolytic activity, transcription fidelity, and ability to pause, arrest, and terminate RNA synthesis. On the other hand, *Eco* β contains two domains that are absent in the *Taq/Tth* β : a 115-residue element (β -SI1) inserted into lobe-2 between conserved regions B and C and a 99-residue segment (β -SI2) inserted into lobe-1 between conserved regions G and H. The high-resolution structures of these domains have been recently solved and modeled into the cryo-EM map of *Eco* RNAP (Figure 1(e)). *Eco* β -SI1 contributes to efficient promoter escape by RNAP; it is also targeted by the bacteriophage T4 termination factor Alc, which selectively induces premature transcription termination on *E. coli* DNA. The role of β -SI2 is currently unknown.

Conformational Flexibility

The structural organization of RNAP can be viewed as a combination of stationary (or fixed) and mobile modules. The fixed core module comprises two α NTDs, ω and the bulk of β and β' subunits that carry the catalytic site and form the back wall of all three channels. The mobile modules include elements associated with binding nucleic acids: the upstream and the downstream portions of β' pincer (the N-terminal σ -binding clamp with rudder and switch-2, and the C-terminal dsDNA-binding β' clamp, respectively); the top β pincer (β lobe-1 and lobe-2 carrying β fork-1 and -2); parts of the active center (β' bridge-helix and trigger-loop); and parts of the RNA exit channel (β flap, β' N-terminal Zn-finger, β' zipper, β' lid). These mobile modules confer considerable conformational

flexibility to RNAP structure: the swinging motion of the β and β' clamps, inferred from comparing the structures of *Taq* and *Eco* core enzymes, results in the opening of the claws by ~ 25 Å. This opening is required for initial σ -subunit binding and to allow the template DNA strand to enter the primary channel and reach the catalytic cleft during transcription initiation. It is also important for σ release during transition to the elongation stage of transcription, and for EC dissociation and transcript release during termination. The subsequent closing of the clamp may help RNAP to tightly hold RNA–DNA hybrid in position during processive elongation.

Structure of RNAP Holoenzyme

The high-resolution structure of bacterial holoenzyme is currently available only with *Tth* σ 70, the major housekeeping σ factor. The *Tth* holoenzyme maintains its overall crab claw-like shape since most of σ is bound on the core surface, except for a short central segment of σ (residues 313–342), which is buried in the core molecule (Figures 2(a)–2(d)). The rest of σ is wedged between the upper (β) and lower (β') pincers at the upstream side of the core enzyme, creating a wall that partially blocks the opening of the primary channel. Transition from core to holoenzyme is accompanied by changes in the positions of several structural domains of core, by 2 to 12 Å. The most noticeable are in the β flap domain (especially β flap tip helix by ~ 12 Å); β lobes-1 and -2, α I-NTD and the β' main channel clamp (~ 4 –6 Å). The RNA exit channel is almost completely blocked by the presence of σ .

Structure of σ

Tth σ 70 and all σ 70-like factors share four regions of sequence homology (1–4), which are further divided into subregions (Figure 2(e)). All conserved regions have been implicated in interactions with core and/or DNA. The visible portion of *Tth* σ 70 resembles a curly bracket-shaped structure. It consists of three α -helical domains σ 2, σ 3, and σ 4, and the linker domain σ 3–4. Domain σ 2 comprises four helix–turn–helix (HTH) motifs, encompassing conserved regions 1.2–3.0 and the large nonconserved segment between regions 1.2 and 2.1. σ 3, comprising three α -helical bundle, contains regions 3.0–3.1. The linker domain σ 3–4 is an extended – mostly unfolded – ~ 30 -residue-long hairpin loop, which includes region 3.2. σ 4 is formed by four α -helices arranged as two HTH motifs, and includes conserved regions 4.1 and 4.2 (Figures 2(d) and 2(e)).

σ –Core Interactions

Domains σ 2– σ 4 are located on the enzyme's surface, wedged between the upper (β) and lower (β') pincers at the upstream opening of the primary channel (Figures 2(a)–2(d)). The hairpin loop of σ 3–4 threads through the primary channel reaching the catalytic pocket and comes out from the RNA exit channel. In the holoenzyme, the σ 2, σ 3, and σ 4 domains are situated at an optimal distance to contact the -10 , extended -10 region, and -35 elements of the promoter DNA in RPC, respectively. The location of domain σ 1 containing the

Figure 2 Structural overview of *Tth* RNAP holoenzyme. The structures are shown as molecular surface (a–c) and ribbons (d, e) views using Accelrys DS Visualizer program, with color coding as follows: α I, light gray; α II, slate gray; β , yellow; β' , cyan, σ , magenta, ω , dark cyan. Locations of functionally relevant domains and structural elements are indicated. The Zn^{2+} ion bound in the β' Zn-finger domain is shown as small blue sphere and catalytic Mg^{2+} ion is shown as red sphere. The N-terminal domain of σ carrying region 1.1 missing from the structure is not shown. (a, b, d) The back (RNA-exit channel) view of the holoenzyme. (c) The front (secondary channel) view of holoenzyme is obtained from (a) by $\sim 180^\circ$ rotation about the y -axis. (b) The view of holoenzyme as in (a) with β removed to reveal the inside of the RNA exit channel and σ 3–4 (colored light magenta) buried in it. The location of all visible σ domains is indicated. (e) The structural and functional organization of σ . Top panel is a ribbon view of σ 70 from *Tth* holoenzyme structure shown in (c). Colored regions correspond to the evolutionarily conserved domains of σ as shown in the functional map of σ 70 below. Bottom panel is a linear representation of σ polypeptide with structural domains and conserved regions shown as numbered and color-coded boxes. Underneath is a diagram of DNA promoter regions and interactions made by DNA-binding domains of σ .

unresolved N-terminal portion of σ (residues 1–73), with poorly conserved region 1.1, in the structure of *Tth* holoenzyme is currently unknown. Biochemical and biophysical data suggest that $\sigma 1.1$ possesses autoinhibitory and regulatory functions. In free σ , $\sigma 1.1$ interacts with $\sigma 4$ and blocks σ factor from binding to DNA. In the holoenzyme, $\sigma 1.1$ facilitates the initial association of σ with core and modulates the efficiency of transcription initiation at some promoters.

The σ -core interaction interface covers an extended surface area with multiple cooperative contacts between discrete domains of σ and different parts of the core. This is likely to be the reason for the high stability of the σ -core association ($K_D = 10^{-9}$ M). However, most of these contacts are relatively weak and are distributed over a large area. This explains why different σ factors successfully compete with $\sigma 70$ for binding to core. The strongest interactions are observed between conserved regions 2.1 and 2.2 of $\sigma 2$ and the N-terminal coiled-

coil domain (β' 540–585) of the β' main channel clamp – the major σ docking site (Figure 2(d)). Multiple contacts of β' NCD1 with σ 1.2 and the nonconserved region of σ 2 also contribute to more stable *Tth* σ 70 binding. Additional, although weaker, interactions occur between β flap and σ 4 [53], and between σ 3 and β lobe-1 (Figure 2(d)). In the presence of specific activators, σ 4 also interacts with α -CTD.

All reported crystal structures of RNAP core and holoenzyme still lack a few elements, the most notable of which is an ~80-residue-long α CTD with a ~14-residue flexible linker connecting it to the α NTD. However, the structures of *Eco* α CTD in complex with *Eco* transcriptional activator CAP and DNA are now available, and its position in RNAP is modeled using cryo-electron microscopy structures of *Eco* RNAP–open promoter DNA complex (Figure 3). The α I— and α II— CTDs recognize and bind the upstream (UP) promoter element and serve as targets for many transcriptional activators.

Figure 3 RNAP holoenzyme-promoter DNA complexes. Structural models of *Taq* RPC (a) and RPO (b, c) with Plac promoter DNA (endpoints -65; +25) and α I- and α II-CTDs are shown as molecular surfaces generated by Accelrys DS. The color coding are the same as in **Figure 2**, except for σ which is colored pink. Structural elements of σ , α CTDs and β' involved in interactions with DNA are indicated by different colors. DNA is shown in stick representation with T and NT strands colored dark green and light yellow, respectively, except for promoter elements colored as indicated. Small magenta balls indicate the position of catalytic Mg^{2+} ions. The β' -NCD1 is not shown. (a) Model of *Taq* RPC. Left panel, the RNA exit channel view of RPC (same as in **Figure 2(a)**). Right panel, the bottom (rim of the exit channel) view of RPC, obtained by $\sim 140^\circ$ rotation of the left view about the x-axis. (b) Model of *Taq* RPO is shown with β removed to reveal the inside of the main channel and to show the interactions of σ and β' elements with transcription bubble and downstream DNA. The view is similar to the left view shown in (a) but rotated by $\sim 60^\circ$ about the x-axis. (c) Zoomed-in detailed view of (b) showing σ -promoter DNA interactions. The inset panel shows the full view of RPO and location of β lobe-1 and -2 that close the main channel and block the access to transcription bubble. The view is obtained by rotation of (b) by 90° about y-axis and tilted backward by 25° .

Structure of Holoenzyme–Promoter DNA Complexes

The high-resolution structures of RNAP–DNA binary complexes are yet unavailable. However, the model structures of the RNAP–closed promoter complex (RPC) and the RNAP–open promoter complex (RPO) were reconstructed from low-resolution (~ 15 – $20\text{\AA}$) cryo-electron microscopy studies of *Eco* holoenzyme–*lacUV5* promoter open DNA complexes, and from crystallographic studies of *Eco* CAP– α CTD–DNA complex, *Taq* $\sigma 4$ domain in complex with a DNA fragment containing –35 element (–26 to –37), and of *Taq* holoenzyme binary complex with fork-junction promoter DNA (containing dsDNA from –12 to –45, and ssDNA from –11 to –7) which partially mimics the RPO. The resulting models of RPC and RPO are consistent with most of the biochemical, biophysical, and genetic data accumulated in the last 20 years.

Closed Promoter Complex (RPC)

In the modeled structure of *Taq* RPC, the promoter dsDNA is located on the surface of holoenzyme, outside the RNAP main channel, bound mostly by σ (Figure 3(a)). In RPC the dsDNA is shielded by RNAP from position –55 to –6. Downstream of position –5 dsDNA does not interact with RNAP. All major DNA sequence-specific contacts in RPC, conserved –10, extended –10, and –35 elements of the promoter, are mediated by the $\sigma 2$, $\sigma 3$, and $\sigma 4$ (regions 2.2–2.4, 3.0, and 4.2, respectively) through polar and van der Waals contacts (Figures 2(e) and 3(a)). Specific σ –DNA contacts are summarized in Table 2. Depending on the length of the spacer and the presence of noncanonical sequence elements, the $\sigma 3$ region 3.0 and β' zipper (residues R35, T36, and L37) may contribute to recognition of noncanonical –15 enhancer element, whereas α CTDs (residues R265, N294, and K298) contact A/T-rich sequences at positions from –45 to –65 and up to –90. Because dsDNA is not fully encircled by RNAP in RPC, and because DNA contact area is relatively small and most of the protein–DNA interactions are weak, the RPC is intrinsically unstable. It is sensitive to salt ($>0.2\text{ M NaCl}$) and competitors such as heparin, and can easily dissociate. Though weak, these interactions provide initial promoter recognition by RNAP and increase promoter occupancy. They also cause significant distortion in DNA structure, thereby facilitating further steps in transcription initiation: DNA melting, strand separation, and template strand insertion into the active site cleft. In the RPC the RNAP-bound DNA is

bent or kinked at three places: around –25 (by $\sim 8^\circ$ to accommodate variable spacer length), at the –35 (by $\sim 36^\circ$ induced by insertion of $\sigma 4$ HTH motif into the major groove), and at further upstream of –45 induced by α CTD–DNA minor groove interactions. The DNA bending at –35 aids in proper binding of upstream DNA by α CTD and upstream transcription activators.

Open Promoter Complex (RPO)

The proposed structure of RPO includes both the dsDNA and the ssDNA covering positions from –60 to +25. Unlike RPC, in RPO both strands of DNA up to +20 position are fully enclosed inside the RNAP main channel (Figures 3(a)–3(c)). The RNAP interactions with the upstream portion of dsDNA (from –60 to –17) are similar to that observed for RPC; however, at –16 the DNA trajectory changes due to a sharp bent by 37° toward the RNAP. At position –11 the template (T) and nontemplate (NT) DNA strands separate, and enter different paths for ~ 15 downstream nucleotides until they reanneal at position +3, thus creating the transcription bubble.

Thermal fluctuation and free energy accumulated in the holoenzyme are believed to be sufficient for DNA melting and transcription bubble formation. The initial DNA melting starts at the A/T bp at position –11. Conserved aromatic residues located on the surface of σ region 2.3, *Tth* F248, Y253, W256, W257, and T252 are positioned near the dsDNA–ssDNA junction of the transcription bubble. The nucleotide bases at –8/–9 and –9/–10 interact with F248 and Y253, respectively, whereas W256 and/or W257 stack on the exposed face of the –12 bp, forming the upstream edge of the transcription bubble (see Table 2). Also, W256 is responsible for capturing the exposed, or flipped A base at the key position –11 of the NT-strand, thereby facilitating DNA melting. The DNA NT-strand (from –2 to +4) further continues its path in a groove formed between β lobe-1 and lobe-2 modules (Figures 3b and 3(c)). The conserved $\sigma 1.2$ basic residues (K215, K216, and R208) are implicated in interactions with DNA at positions from –6 to –4 of the DSR region. These interactions stabilize the RPO formation and accelerate transcription initiation at some promoters. Another cluster of conserved basic residues (R259, K285, R288, and R291) of $\sigma 2.4$ and $\sigma 3.0$ is proposed to pull the DNA T-strand (from –7 to +3), through electrostatic interactions, into a groove formed by $\sigma 3$, β' lid, and the β' rudder (Figure 3(c)). The DNA is then placed into the main channel between the active site wall and $\sigma 3$ –4 hairpin loop. Conserved charged

Table 2 Summary of σ –DNA contacts

DNA position (T, NT) ^a	<i>Taq</i> $\sigma 70$ residues	$\sigma 70$ Region (domain)
Major groove at –12A, –12T (base specific)	Q260, N 263	2.4 ($\sigma 2$)

residues at the tip of the hairpin participate in juxtaposing DNA +1 position to the catalytic center and assist in correct placement of the initiator rNTP (Figures 3(b) and 3(c), Table 2). Simultaneously, the dsDNA downstream of +3 to +12 is brought inside the downstream DNA binding clamp between the β' jaw, β lobe-2, and the downstream β' clamp. The β' switch-2, a small flexible loop residing in the upstream β' clamp in the middle of the main channel cavity, controls the binding of the downstream part of the unwound DNA T-strand in the active site cleft. Switch-2 functions as a hinge mediating opening and closing of the β' clamp, and plays a critical role in downstream propagation of transcription bubble during formation of RPo. It serves as a primary target for the action of antibiotic Myxopyronin (Myx) which binds to β' switch-2 and prevents its refolding. Thereby, Myx interferes with opening of the active center cleft, and blocks entry and unwinding of the downstream DNA. Finally, β lobes-1 and -2 move toward β' clamps by 6–8 Å, which leads to substantial reduction of the main channel opening. This closing hampers DNA dissociation and prevents the collapse of the transcription bubble. Thus, a stable, competitor-resistant and initiation-competent RNAP–promoter DNA complex is formed.

Structure of EC

Several high-resolution structures of bacterial ECs are currently available: (1) the 2.5-Å-resolution structure of *Tth* RNAP core in complex with a synthetic nucleic acid scaffold containing 14-bp-long downstream dsDNA, 9-bp-long RNA/DNA hybrid, and 7-nt-long ssRNA (*Tth* EC); (2) the 3-Å-resolution structures of *Tth* EC co-crystallized with nonhydrolyzable substrate analog, adenosine-5'-[(α,β)-methyleno]-triphosphate (AMPcPP), and with AMPcPP plus antibiotic streptolydigin (Stl); and (3) the 4.1-Å-resolution structure of *Tth* EC with a comparable RNA/DNA scaffold but containing an additional 24-nt-long RNA hairpin, co-crystallized with transcription factor Gfh1. These structures collectively offer a detailed view of the bacterial EC architecture, and help elucidate the mechanisms of RNAP catalysis, that is, substrate binding, incorporation, and enzyme translocation. The structures also provide insights on how the interactions between various structural elements of RNAP, the nucleic acids, substrates, and regulatory molecules determine EC's stability, high processivity, and response to signals encoded in DNA and RNA. Together with the knowledge gained from the structural studies of eukaryotic ECs we have greatly expanded our understanding of the transcription process carried out by multisubunit RNAPs.

Structural Organization of EC and Protein–DNA/RNA Interactions

The structures of *Tth* EC show that 13 bp of the B-form dsDNA resides in the downstream DNA-binding cavity, constricted between the downstream β' clamp, the β' jaw and β lobe-2 (Figure 4(a)). The downstream dsDNA makes very few direct polar contacts with RNAP. Most of the RNAP–DNA interactions including electrostatic and hydrophobic are weak and nonspecific (Table 3); this endows EC with fast translocation and high processivity. The T-strand DNA makes a sharp $\sim 90^\circ$ kink at the junction between the downstream dsDNA and

RNA/DNA hybrid. The kink is induced by the protein barrier in the form of the β' bridge helix and β fork-1 and -2 (Figures 4(a) and 4(b)). The β' rudder loop residing between the dsDNA and DNA/RNA hybrid stabilizes their position and conformation via direct electrostatic contacts (Table 3).

The 9-bp RNA/DNA hybrid is placed at the back wall of the main channel, snugly packed between the upstream β' clamp, β' rudder, and β lobe-1. The hybrid is surrounded by the most conserved structural elements in RNAP including β' DPBB domain with the Mg^{2+} -binding catalytic loop, β' switch-2, β DPBB domain with substrate-binding loops, β switch-3, β RNA-binding helix, β fork-1 with fork-1 helix, and β fork-2 (Figure 4(c)). The latter four elements of β -subunit bind antibiotics Rifampicin (Rif) and Sorangicin (Sor), which strongly inhibit the early steps in RNA synthesis. They act by blocking the path of the growing transcript beyond the length of 2–3 nt, thereby locking RNAP in abortive initiation complex. There are numerous of mixed-mode polar and van der Waals contacts between the phosphate backbone of RNA/DNA hybrid and the conserved basic and hydrophobic residues of the hybrid-binding pocket, respectively (Table 3, Figure 4(c)). These interactions provide an optimal combination of repulsion and attraction forces that ensures a sterically tight placement of the hybrid in the active site cleft, without excessive binding of the nucleic acids. The β fork-2 participates in dsDNA melting by stacking R422 on base pair at $i+2$ register and inducing DNA strand separation (Figures 4(b)–4(d)).

The nascent RNA is separated from the T-strand DNA by the β' lid which sterically blocks the expansion of RNA/DNA duplex beyond 9 bp and fixes the upstream edge of transcription bubble. The β switch-3 also participates in RNA separation by trapping the first displaced RNA nucleotide. The 7-nt-long ssRNA is threaded through the RNA exit channel making weak interaction with the surrounding upstream elements: the β' zipper, β' N-terminal Zn-finger, β' rim helix, and β flap elements (see Table 3, Figures 4(c) and 4(d)).

Compared to the structures of core or holoenzyme, the β' clamp modules in EC are shifted toward β lobes by ~ 4 –6 Å. The closing motion of the clamps substantially reduces the main channel aperture and blocks the access to the RNAP active center. This implies that the unobstructed secondary channel serves as the main conduit for substrates and by-products of RNA synthesis. The observed closure of the clamps also explains the remarkable stability of the EC, for example, its resistance to salt (up to 2 M NaCl) or polyanion DNA competitors (150 $\mu\text{g ml}^{-1}$ heparin).

Structural Rearrangements at the Active Center

The structures of *Tth* ECs are captured in the post-translocated state: the 3'-terminal RNA nucleotide, base-paired with the $i-1$ template DNA base, resides in the active site coordinated by one of the two catalytic Mg^{2+} -ions (Figure 4(e)). The unpaired $i+1$ template DNA base is stacked between the $i-1$ nucleotide of the template and the β' bridge helix, and is positioned in the active site for base pairing with the incoming substrate rNTP (Figure 4(e)). Since the $i+2$ register is base-paired, the substrate can bind only to a single base-specific site, $i+1$. The structure of *Tth* ECs with the nonhydrolyzable substrate analog AMPcPP is consistent with this view (Figures 4(e) and 4(f)).

Figure 4 Structure of EC and implications for transcriptional mechanisms. (a) Overall structure of *T7h* EC showing the location and trajectory of nucleic acids. Left panel, the main channel view of EC in ribbon representation. The color code is same as in **Figure 1(a)**. RNA, red; DNA T strand, dark green; DNA NT strand, light yellow. Middle and right panels are the molecular surface views of EC (white) with nascent RNA and RNA/DNA hybrid (shown as colored semitransparent ribbons with sticks) completely buried inside RNAP main channel. Views of the left and middle panels are the same. View in the right panel is obtained by rotation of the middle panel as indicated. (b, c, and d) Close-up view of the RNAP structural elements involved in interaction with the downstream dsDNA (b), RNA/DNA hybrid (c), and nascent RNA (d). Views in (c) and (d) are obtained by rotation of view shown in (b) about vertical and horizontal axis, as indicated. (e) Nucleic acid scaffold and mobile structural elements at the active center. The view is obtained by rotating the view in (b) around y -axis by $\sim 180^\circ$ and tilting forward by $\sim 90^\circ$. The nucleic acids end points and positions of DNA T strand bases at registers -1, +1, and +2 are indicated. Bridge helix and trigger loop are represented as colored ribbons. Trigger loop is shown in two alternative conformations: as folded helices (visible in *T7h* EC-AMPCPP structure), and as unfolded loop (visible in holoenzyme structure), colored blue and cyan, respectively. Substrate AMPcPP bound at the insertion site, yellow sticks; catalytic Mg^{2+} ions, magenta spheres; bridge helix, magenta ribbon. (f) The close-up view of the key components of the catalytic center substrate-insertion site. The view is derived by tilting the view shown in (e) forward by $\sim 20^\circ$. The DNA, RNA, and AMPcPP are represented as cyan, magenta and yellow stick, respectively. Four groups of residues are shown: those that coordinate Mg -I and Mg -II directly (red) or indirectly (orange), those that participate in binding and proper orientation of α -, β -, and γ -phosphates of rNTP (blue), and those responsible for recognition of correct rNTP (light green). (g) Diagram showing the sequential steps of nucleotide addition cycle (NAC). DNA and RNA are depicted as bars, colored coded as in (a-e). Trigger loop, cyan circles connected by long dashed line; trigger helix, blue circles connected by short line; bridge helix, purple circle; Mg^{2+} ions, small magenta circles; rNTP, short orange bar with three small circles (phosphates).

Table 3 Summary of protein–DNA/RNA contacts in EC

	<i>RNA or DNA position (T, NT)^a</i>	<i>Tth β or β' residues</i>	<i>RNAP structural element</i>
Nascent ssRNA	–16 Base	β E770, L773	β Flap tip helix
	–16/–15 Phosphate	β' K671	β' Exit channel rim helix
	–14/–13/–12 Phosphates	β E764	β Flap tip helix
	–12/–11 Phosphate	β Y1013	β Helix–loop–helix
RNA/DNA hybrid	–10/–9 Phosphate	β' R601	β' Rudder
	–9 Base, –9 base	β' A536, V530	β' Lid
	–9/–8 Phosphate	β' R534	β' Lid
	–9/–8 Phosphate, minor groove	β R388	β Lobe-1 loop
	–8, –9 Minor groove	β' R598	β' Rudder
	–8/–7 Phosphate, major groove	β' Q611	β' Switch-2
	–7/–6/–5 Phosphate, minor groove	β Q390, Q393	β Lobe-1 loop
	–5/–4 Phosphate	β N448, R409	β Fork-1
	–4/–3 Phosphate	β R409, R405	β Fork-1 helix
	–4/–3 Phosphate, minor groove	βE1002*, V1001*	β Switch-3
	–3/–2 Phosphate	β Q567, N563	β Rifampicin-binding helix
	–3/–2 Phosphate	β K846	β DPBB domain
	–3/–2 Phosphate	β' R628, R622	β' DPBB domain
	–3/–2 Phosphate	β Q1030, R1031	β Switch-3
	–2/–1 Phosphate	β K846	β DPBB domain
	–2/–1 Phosphate	β' R704	β' DPBB domain
	–2/–1 Phosphate	β Q1030, R1031	β Switch-3
	–2/–1 Phosphate	β' R621	β' DPBB domain
Downstream dsDNA	–1/+1 Phosphate	β' R615	β' Switch-2
	–1/+1 Phosphate	β' R1096	β' Bridge (F) helix
	+1/+2 Phosphate, base	β' G1092, A1089	β' Bridge (F) helix
	+1/+2 Phosphate	β' K610	β' Switch-2
	+2, +2 Base	β R422	β Fork-2
	+2/+3 Phosphate	β' R1096, Y1093	β' Bridge (F) helix
	+3/+4 Phosphate	β' Y1093	β' Bridge (F) helix
	+3/+4 Phosphate	β' Q1441	β' Clamp C-terminal HLH-loop
	+4/+5 Phosphate	β' N1442	β' Clamp C-terminal HLH-loop
	+4/+5 Phosphate	β' R586	β' Rudder
	+4/+5/+6 Phosphate	β' K1266	β' Jaw
	+5/+6 Phosphate	β' K106	β' Clamp N-terminal HLH-loop
	+8/+9 Phosphate, minor groove	β' V108*	β' Clamp N-terminal HLH-loop
	+12/+13 Phosphate, minor groove	β' R486, A487*	β' Downstream clamp helix
	+13/+14/+15 Phosphate	β' R488	β' Downstream clamp helix

^aUnderlined text is RNA; roman text is DNA position T, and italic text is DNA position NT.

AMPcPP binds to EC at the insertion site of the catalytic center where it stacks on the *i*–1 RNA base and forms a base pair with the *i*+1 acceptor template, while its phosphates coordinate two essential Mg²⁺ ions that play a key role in RNA catalysis (Figures 4(e) and 4(f)). In the *Tth* EC–AMPcPP complex the substrate binding induces a refolding of the partially disordered trigger loop (an open conformation observed in the holoenzyme structure) into two α -helices (a closed catalytically active intermediate). Together with the adjacent bridge helix present in straight α -helical conformation, this creates a transient three-helical bundle (Figure 4(e)), which constricts the secondary channel and hinders substrate dissociation. This process is common to all multisubunit RNAPs. Other changes in the EC structure include minor repositioning of the β fork-2 toward the active site (by ~ 1 Å), and a shift of the β' bridge helix (by ~ 1.5 Å) to stabilize the β' trigger helices.

It should be noted that in addition to straight, continuously helical conformation, β' bridge helix can adopt alternative

conformations where its central part has a kink or is flipped out, as observed in the structures of *Taq* core, *Tth* holoenzyme, and *Tth* EC–Gfh1 complex. However, the functional significance of these conformations is unclear. Similarly, in some structures of *Tth* EC as well as yeast RNAP (Pol II EC), the trigger loop displays several partially folded conformations, which appear to be intermediate between fully folded α -helices and unfolded loop, as depicted in (Figure 4(e)). It was proposed that the intermediate conformations of trigger loop (and bridge helix) play an important role for transcription pausing, termination and for the action of transcription factors binding in the secondary channel (such as GreA/B, DksA, and Gfh1).

Structure of the Catalytic Site

At the center of the catalytic site are two essential Mg²⁺ ions (high-affinity Mg-I and low-affinity Mg-II) that play a key

role in RNA catalysis. The two Mg^{2+} ions are surrounded by four highly conserved structural elements of RNAP: the stationary β' DPBB domain with several conserved adjacent loops and helices including the catalytic loop; the stationary β DPBB domain; and the mobile β' bridge helix and β' trigger loop. The high-affinity Mg-I is stably bound in RNAP by a triad of Asp in the β' catalytic loop (D739, D741, and D743) (Figure 4(f)). It is primarily responsible for activation of RNA 3'-terminal OH group and for coordination of the α -phosphate of AMPcPP in the insertion site. The low-affinity Mg-II is held at the insertion site of *Tth* EC, proximal to the location of Mg-I (at a distance of ~ 3.9 Å), mostly by D739 of the β' catalytic loop via direct interactions. Also, residues E685 and D686 of the β DPBB domain and D741 of the β' catalytic loop may contribute to stabilization of Mg-II through additional water-mediated contacts. Mg-II coordinates all three rNTP phosphates providing their optimal spatial alignment for nucleophilic attack of activated 3'-OH group on the α -phosphate. Additionally, the β - and γ -phosphates of rNTP (or pyrophosphate) are stabilized by contacts with basic residues of the β' trigger loop (R1239), β' DPBB domain (R783), β' clip-1 loop (R1029), and β DPBB domain (R879) via hydrogen bonding and electrostatic interactions (Figure 4(f)). The H1242 of the β' trigger loop contacts α -phosphate of rNTP (during RNA synthesis) or the phosphate between RNA $i-1$ and $i+1$ nucleotides (during pyrophosphorolysis and hydrolysis). This interaction greatly facilitates the nucleophilic attack of the 3'-OH group (or the OH^- ion or the water molecule) and is essential for all enzymatic reactions catalyzed by RNAP, that is, RNA synthesis, pyrophosphorolysis, and nucleolytic hydrolysis. To ensure incorporation of correct nucleotides into the RNA, M1238/F1241 residues of the β' trigger loop and T1088 of the β' bridge helix make stacking and hydrophobic/van der Waals contacts with rNTP base and DNA base at $i+1$ position, respectively, while N737 and R704 of the β' catalytic loop establish hydrogen bonds with 2'- and 3'-OH groups of the ribose ring of NTP (Figure 4(f)).

Tth EC-AMPcPP-Stl complex captures AMPcPP in an intermediate preinsertion site in the active center. In the structure, Stl resides in the pocket formed between the β' bridge helix/trigger helix bundle, β fork-2, and the downstream dsDNA ($i+1/i+4$). The Stl binding leads to displacement of the trigger helix from the insertion site, inducing its unfolded (open) conformation. In the absence of the folded trigger helices, the AMPcPP is found in the preinsertion site. It still maintains proper base-pairing with $i+1$ DNA base; however, positions of the α -, β -, and γ -phosphates together with the bound Mg-II ion are shifted by 2–2.5 Å away from Mg-I to a distal location (at a distance of ~ 6.4 Å), due to a $\sim 35^\circ$ rotation around the C4'-C5' bond of the ribose. These observations suggest that AMPcPP binds to EC first in the preinsertion site in an inactive substrate configuration, and, then, in response to trigger helix folding, it isomerizes into a catalytically competent insertion site.

Structural studies revealed that by blocking the folding of the trigger helix, Stl interferes with one of the key steps of nucleotide addition cycle (NAC), thereby inhibiting RNA synthesis. A similar mechanism of action is ascribed to another antibiotic, Tagetitoxin (phytotoxin), which also binds at the base of the secondary channel near the active center and inhibits conformational cycling of trigger loop/trigger helix.

NAC and the Mechanism of Translocation

The high-resolution structures of substrate-bound *Tth* EC offer two key findings:

1. The mobile β' trigger loop/trigger helix is the second essential component of the catalytic center (after the main Mg^{2+} -binding β' catalytic loop). It alternates between the substrate-induced catalytically active α -helical conformation (trigger helix) and the inactive unfolded conformation (trigger loop).
2. In the presence of Mg^{2+} -ion, rNTP can occupy two alternative sites in EC – the catalytically active insertion site stabilized by the trigger helix, and the inactive preinsertion site.

These findings led to a model of NAC and RNAP translocation as illustrated in Figure 4(g). At the beginning of NAC, the EC exists in thermodynamic equilibrium, oscillating between the pretranslocated and posttranslocated states. The rNTP- Mg^{2+} first binds to EC and stabilizes it in a posttranslocated state acting as a ratchet (Figure 4(g), step 1). The binding occurs in a template-dependent manner at the $i+1$ register in the preinsertion site, when the β' trigger loop is in an open, unfolded conformation. Mg-II, coordinated by the three phosphates of rNTP, is placed at a distal position relative to Mg-I, and the preinsertion inactive intermediate complex is formed (step 2). Next, rNTP induces the folding of the trigger loop into a helix, displacing the β' bridge helix and β fork-2, and shifting the position of Mg-II/rNTP triphosphate to a site proximal to Mg-I. This leads to isomerization of EC into the catalytically competent, closed insertion state (step 3). After completion of the catalytic nucleotidyl transfer reaction and transcript extension, the EC transforms into closed, pretranslocated state (step 4). Next, the pyrophosphate-Mg-II complex is released from EC causing destabilization and unfolding of the β' trigger helix. This results in transition of the EC to the pretranslocated state with an open conformation of the trigger loop (step 5). In the last step of NAC, the EC undergoes reversible translocation and returns to the open, posttranslocated ground-state EC capable of binding new rNTP (step 6).

Structural, biochemical, and biophysical data indicate that the energy of NTP hydrolysis is not directly used for EC translocation during elongation. RNAP moves as a Brownian ratchet machine driven forward only by the energy gained from binding the correct substrate. The concerted action of rNTP binding at the catalytic site, the β' trigger loop folding/unfolding and the step-wise transcript extension makes RNAP movement unidirectional. The correct incoming rNTP works as a stationary pawl in the Brownian ratchet preventing RNAP from slipping backward, whereas the β' trigger loop together with the bridge helix and β fork-2 act as a reciprocating pawl, pushing RNAP forward relative to the DNA/RNA scaffold. This system of two pawls couples the forward motion of RNAP with efficient incorporation of correct substrate without falling out of register, nucleotide skipping, or RNA slippage.

Future Prospects

In the past 5 years a great progress has been made in our understanding of the structure and function of bacterial

RNAP, especially its complexes with nucleic acids in the presence of substrates and regulatory molecules. However, our knowledge of RNAP mechanics is still fragmented. Many important details concerning the mechanisms of transcription initiation and termination and their regulation remain to be elucidated. The wish list of RNAP structures that would help address many long-standing questions include complete high-resolution structures of RPc, RPo and their intermediates, EC in pretranslocated state with resolved nontemplate ssDNA and upstream dsDNA, ECs locked in paused and arrested (backtracked) states, termination and anti-termination complexes and their intermediates, and RNAP complexes together with transcription factors, regulatory RNAs, antibiotics, and other small molecules that modulate RNAP activity.

Glossary

Branch point adenosine A specific adenosine in an intron, the 2' hydroxyl of which forms a 2'-5' phosphodiester linkage with the 5' base of the intron during the first chemical step of splicing.

Exon Regions of pre-mRNAs that can be retained in mature messenger RNAs (mRNAs) following splicing.

Introns Noncoding regions of pre-mRNAs that are excised by the splicing process.

Phosphodiester transfer The chemical process in which one phosphodiester bond is broken and another is formed simultaneously.

Polypyrimidine tract The region between the branch point adenosine and 3' splice site, which is rich in cytosine and uridine residues.

Pre-mRNA The primary transcript of a gene synthesized by RNA polymerase II. The primary transcript extends from transcription initiation site to beyond the 3' end of the mature mRNA. It is subject to several processing events including splicing.

Ribozyme An RNA molecule that is capable of catalyzing a chemical reaction.

Spliced-leader A short RNA transcript that is spliced to the 5' end of pre-mRNA transcripts in several species of trypanosomes.

3' splice site The boundary between an exon and the end of an intron.

5' splice site The boundary between an exon and the beginning of an intron.

The study of RNA splicing has impacted several fields of biological research. The discovery of a variety of forms of splicing, including alternative splicing, trans-splicing, and self-splicing sequences, has provided new insights into the increasingly complicated web of gene regulation and the evolution of genomes. Investigations into the molecular mechanisms of the splicing of eukaryotic genes have revealed a complex cellular machinery responsible for the process known as 'splicing'. Furthermore, because splicing is important to the expression of nearly all of human genes, a large number of genetic diseases are linked to splicing. As our understanding of the process advances further, opportunities for developing therapeutic interventions for those diseases will likely arise.

Observation of Split Genes Lead to the Discovery of Splicing

In 1977, Phillip Sharp and Richard Roberts independently reported that eukaryal messenger RNAs (mRNA) do not contain long stretches of sequence that are present in the encoding DNA. These sequences were called 'intervening sequences' and later renamed 'introns'. At first glance, the presence of introns in genes presented a conundrum to the understanding of gene expression at that time, which was encompassed by the central dogma of molecular biology. These inconsistencies were resolved when it was discovered that intron sequences were precisely removed from precursor RNA transcripts (pre-mRNA) while at the same time the flanking sequences, now called 'exons', were joined together into a continuous mRNA before export to the cytoplasm for translation. It is now widely recognized that many eukaryotic genes are not strictly continuous stretches of protein-coding sequence forming intact open reading frames, but rather, that the coding sequences are

interrupted by intron sequence with no obvious function. The intron sequence is precisely removed from RNA transcripts of the genes by the process of pre-mRNA splicing, which results in creation of mRNA with intact open reading frames (Figure 1). Splicing, therefore, is an essential step in the flow of genetic information in eukaryotic cells.

The Chemistry of Pre-mRNA Splicing

Understanding of the chemical mechanism of pre-mRNA splicing was primarily derived from the use of an *in vitro* splicing assay in which a simplified pre-mRNA substrate could be biochemically analyzed. This *in vitro* assay includes a radiolabeled synthetic RNA that is incubated in an extract from the nuclei of the HeLa cell line. Under the appropriate conditions, the splicing machinery within the HeLa nuclear extract recognizes the single intron in the RNA and catalyzes its removal while joining the two flanking exons together. With this system, the basic chemistry of splicing was elucidated to consist of two coordinated phosphodiester transfer reactions (Figure 2). First, the 2' hydroxyl of a specific adenosine residue in the intron attacks at the boundary of the upstream exon and intron, breaking the phosphodiester bond at that site, while creating a new 2'-5' phosphodiester bond between the adenosine and the 5' end of the intron. The reaction loops the intron around the adenosine creating a branched structure at the adenosine called a 'lariat'. Following this first reaction, the newly exposed 3' hydroxyl of the upstream exon attacks at the boundary of the intron and downstream exon. This event creates a normal phosphodiester linkage between the exon sequences and releases the intron in lariat form. The two sites of cleavage at the ends of the intron were termed the '5' and 3' splice sites' and the internal adenosine involved in the first chemical step is known as the 'branch point'.

Figure 1 The central dogma of molecular biology explains the transfer of genetic information from DNA → RNA → protein. In the nucleus of a eukaryotic cell, DNA is transcribed to produce pre-messenger RNA (pre-mRNA). By the process of splicing, introns (depicted lines) are removed and exons (depicted as boxes) joined to create messenger RNA (mRNA). The mRNA is then exported to the cytoplasm and translated into protein.

Figure 2 Splicing occurs through two coordinated phosphodiester transfer reactions. In the first chemical step of splicing the 2'-hydroxyl of an adenosine residue (A) within the intron attacks the 5' splice site (5' ss). This reaction produces the intermediate species of pre-mRNA splicing: cleaved 5' exon and lariat intermediate. In the second chemical step, the 3'-hydroxyl of the cleaved 5' exon attacks the 3' splice site (3' ss). This reaction joins the exons to create mRNA and releases the intron in lariat form.

Splicing Consensus Sequences Designate Introns

The 5' and 3' splice sites as well as the branch point adenosine in the intron are specified by sequence elements within the intron and exons (Figure 3). These sequence elements are evolutionarily conserved from yeast to human. For the majority of metazoan introns the 5' splice site is a partly degenerate sequence, although more conserved in the yeast *Saccharomyces cerevisiae*, which has been an important model organism for splicing studies. Within the 5' splice site sequence, the GU

dinucleotide at the beginning of the intron is invariant from yeast to metazoans. The 3' splice site of the major class of metazoan introns is also degenerate, with an invariant AG dinucleotide at the 3' end of the intron. The adenosine at the branch point is contained within a heptamer sequence that is located near the 3' splice site. Again, the sequence is highly conserved in yeast introns and is more degenerate in metazoans. The branch point sequence is usually separated from the 3' splice site by a region composed mainly of C and U residues known as the 'polypyrimidine tract'. The metazoan polypyrimidine tract varies significantly in length and pyrimidine content, while in yeast the tract is composed primarily of U residues and distance between the branch point and 3' splice site is constrained to about 39 nucleotides. There is evidence that the identity of the polypyrimidine tract can influence splice site usage.

As increased numbers of introns have been sequenced, a second class of intron consensus sequences was identified. This class, termed 'minor class,' is found in both vertebrate and invertebrate metazoans. In contrast to the conserved GU-AG sequences that flank the vast majority of introns described above, the 5' and 3' splice sites have, respectively, AU-AC sequences.

An important point to note about splicing consensus sequences is that they alone do not contain enough information to specify splice sites in the context of the vast amount of intron sequence found in metazoan genes. Additional sequences that flank the splice sites also play a role, although more often in an intron-specific fashion. These different layers of information for defining splice sites echo the structure of eukaryotic RNA Pol II promoters, which contain shared core features and gene-specific regulatory elements.

Exon-Intron Architecture of Eukaryotic Genes

The variation in conservation of splicing sequences between yeast and humans is primarily attributed to the differences in the average length and number of introns in yeast and human genes. Only 283 of the ~6000 genes of *Saccharomyces cerevisiae* contain introns, whereas nearly 95% of human genes are predicted to contain introns. Yeast introns on average range from 100 to 400 nucleotides and, with few exceptions, there is only one intron, and therefore two exons, per intron-containing gene. Typically, yeast introns are located in the 5' end of the gene and are removed contrascriptionally. Although less than 5% of yeast genes contain introns, it is of note that these intron-containing genes represent some of the cell's most highly expressed transcripts.

Human genes contain multiple introns (on the order of 8 per gene) that average 11 000 nucleotides, however, with significant variation in length. By contrast, the average length of human exons is ~200 nucleotides. Splicing of human genes is also likely to be a co-transcriptional process, with the first introns emerging from RNA polymerase being removed first. This coupling likely reinforces the ligation of upstream exons to downstream exons such that the order of exons in the RNA transcript is preserved in the mRNA. With alternative splicing, which will be discussed in a later section, exons can be skipped, but exon order is never rearranged.

Figure 3 Conserved sequences define the splice sites and branch point adenosine of introns. For yeast, these sequences are nearly universally conserved and the distance between the branch point adenosine (red box) and 3' splice site is usually close to 25 nucleotides. In vertebrates, two types of introns are observed: U2 type and U12 type. For these introns, the splicing sequences are more variable. Shown below each sequence is the percent identity for a given nucleotide. (+) indicates nearly 100% conservation. (n) stands for any nucleotide. (Y) stands for pyrimidine, which is either U or C. (R) stands for purine, which is either A or G. (K) stands for either U or G.

In both yeast and humans, the minimal information content of the splice site consensus sequences means that additional factors must play a role in the regulation of splice site choice. However, the weaker conservation of human introns makes splicing even more dependent on additional regulatory factors, allowing for more complex splicing control. This control is important to the extra levels of regulation that arise with the process of alternative splicing in humans. There is growing evidence that an important step in human splice site recognition is the identification of exons and several factors have been shown to bind specifically to exons and participate in recruitment of the splicing machinery.

The Spliceosome Is the Machinery Responsible for Pre-mRNA Splicing

Eukaryotic cells have evolved an elaborate complex, known as the 'spliceosome', to carry out the two chemical steps of the splicing reaction at each intron. The spliceosome is arguably the most complicated machinery in the cell. It assembles on each intron from well over 100 components on each intron in a highly dynamic manner. The key building blocks of the spliceosome are five ribonucleoprotein (RNP) complexes that each contains a U-rich small nuclear RNA (snRNA), shared core components, and several specific proteins. The complexes, called 'snRNPs' or 'snurps,' are named for their snRNA component: U1, U2, U4, U5, and U6. In addition to the snRNPs, a complex associated with the Prp19 protein (NTC for nineteen complex) and a myriad of other proteins are found in spliceosomes. Together these components play critical roles in identifying conserved *cis*-RNA sequences, assembling the catalytic spliceosome and facilitating splicing chemistry. Given the dynamic complexity of the splicing machinery, a detailed understanding of the mechanics, regulation, and three-dimensional organization of the spliceosome remains elusive.

The roles of several components of the spliceosome have been studied extensively. The snRNAs of the spliceosome, in particular, were shown to have central functions in recognizing splice sites and positioning them in the catalytic core of the complex. U1 snRNA forms base pairs with the 5' splice site consensus early in spliceosome assembly. U2 snRNA base-pairs with the branch point sequence to form a short helix from which the branch point adenosine is bulged, likely to

help position its 2' hydroxyl as the nucleophile for the first step of chemistry. U2 makes extensive base pairs with part of U6 snRNA, while another region of U6 replaces U1 snRNA base pairs with the 5' splice site during catalytic activation of the spliceosome. This intricate network of RNA interactions along with critical roles for specific sequences in the snRNAs for splicing has provided fodder for the hypothesis that snRNAs serve as the catalyst of splicing.

As previously described, a minor class of introns exists with different splice site consensus sequences. These are spliced by the minor spliceosome, which shares many of the same components as the major spliceosome, including U5 snRNP. However, instead of U1, U2, U4, and U6 snRNAs, the minor spliceosome makes use of U11, U12, U4-atac, and U6-atac snRNAs, which differ primarily in the sequences that base-pair with the 5' splice site and branch point.

The functions of some proteins in the spliceosome are understood. Much of this understanding comes from genetic and biochemical studies in the yeast *Saccharomyces cerevisiae* where mutations in spliceosome components can be generated and analyzed. For example, a number of RNA-dependent ATPase proteins have roles in rearranging the structures of the snRNAs as the spliceosome is assembled and activated for catalysis. Because of their important roles, mutations in these proteins result in the accumulation of pre-mRNA in the cells. However, for most proteins in the complex, their functions are still unknown. In particular, there appear to be additional protein factors that associate with metazoan spliceosomes that do not associate with yeast spliceosomes, but their roles in splicing are unclear. Likely, the additional complexity of multiple intron-containing metazoan genes and alternative splicing require these proteins for regulation.

Alternative Pre-mRNA Splicing

Soon after the discovery of splicing, it was noted that some splice products of particular gene transcripts differed in the use of splice sites such that the resulting mRNAs carried different sequences. This phenomenon was termed 'alternative splicing' and is now widely recognized as a key point of gene regulation in metazoans. Well over half of the human genes contain exons that are differentially skipped or included in the final mRNA in response to cellular cues. Alternative splicing leads to a highly

diverse set of messages and protein products being produced from a limited number of genes and plays a key role in creating the complexity contained in, for example, the human nervous system. This important process is discussed in more detail elsewhere in this encyclopedia.

Self-Splicing Introns and the Discovery of Ribozymes

Soon after the initial discovery of introns, Tom Cech and colleagues found a remarkable intron in *Tetrahymena thermophila* that was spliced even in the absence of protein factors. They showed that the intron was autocatalytic in that it promoted its own removal from its associated transcript. Termed a 'ribozyme', the enzymatic function of the intron depends on its ability to fold into a three-dimensional structure. The splicing reaction differs from pre-mRNA splicing in the first step of chemistry where a cofactor guanosine nucleotide is bound and positioned by the intron to attack at the 5' splice site. Exon ligation follows with the free 5' exon attacking at the 3' splice site. With group I intron splicing, the intron is released in linear form and capped with the exogenous guanosine (Figure 4). The intron that Cech characterized and evolutionarily related family members found primarily in bacteria and the organellar genes of plants, protists, and fungi are known as 'group I introns'. The sequence conservation among these introns can be primarily attributed to preservation of secondary structure and tertiary interactions that are important for maintaining the active structure of the ribozyme (Figure 5(a)).

Another structurally distinct family of self-splicing introns (group II) has also been characterized. Like group I, these introns are also found primarily in the organellar genes of protists, but have also been identified in bacteria. Also, like group I, the main selective pressure for group II intron sequence

Figure 4 Splicing mechanism for group I introns. The first chemical step of group I intron removal differs from pre-mRNA splicing wherein the 3'-hydroxyl of an exogenous guanosine nucleoside attacks the 5' splice site. Similar to pre-mRNA splicing, the free 5' exon attacks the 3' splice site in the second chemical step. The released intron structure is linear and is capped by the exogenous guanosine.

is preservation of secondary structure and key tertiary interactions that provide the proper stereochemical environment for the two transesterification reactions of splicing (Figure 5(b)). The mechanism of group II intron excision is identical to the splicing of eukaryotic spliceosome introns. A specific adenosine residue in the intron is bulged from a short helix and serves as the nucleophile of the first step of chemistry and produces a lariat intron intermediate. It has also been noted that sequences in group II introns that are essential for catalysis are present in U6 snRNA where they are also important for splicing. The splice site sequences of group II introns (5' GUGYG and 3' AY) also show similarity to spliceosomal introns. Based on these similarities, it is reasoned that group II introns are the evolutionary precursor of the eukaryotic spliceosome.

Although capable of self-splicing *in vitro*, many group I and group II introns require protein cofactors for efficient splicing in cells. In some cases, these proteins are host organism proteins, and in other cases the proteins (termed 'maturases') are encoded by open reading frames located within loop sequences of the intron.

Trans-Splicing

In addition to *cis*-splicing events (transesterification reactions occurring from splice sites within a single transcript), examples of *trans*-splicing events are increasingly reported. A first example is found in trypanosomes, some protists, and some neochordates. In these organisms a short RNA transcript, called the 'spliced leader', is added to the 5' end of protein-coding mRNAs (Figure 6). This addition is accomplished by splicing

Figure 5 Group I and group II introns have conserved secondary structures and complex tertiary structures. (a) Stereotypical secondary structure of group I introns is schemitized on the left and the three-dimensional structure of a group I intron from an *Azoar* bacterial species (PDB: 1ZZN). (b) Stereotypical secondary structure of group II introns is schemitized on the left and the three-dimensional structure of a group II intron from an *Oceanobacillus* bacterial species (PDB: 3IGI).

Figure 6 Mechanism of spliced-leader RNA trans-splicing. The spliced-leader RNA sequence contains a 5' splice site that is attacked by the 2'-hydroxyl of a branch point adenosine in the 5' region of a pre-mRNA known as an 'outtron'. The 3'-OH of the cleaved spliced-leader then attacks at the 3' splice site within the pre-mRNA molecule to join the spliced-leader to the pre-mRNA. The outtron is released as a Y-shaped molecule rather than a lariat structure because of its discontinuous structure.

between a 5' splice site in the spliced leader and a 3' splice site at the boundary of 5' region of the pre-mRNA known as an 'outtron' and the following exon. The spliceosomal U snRNPs are responsible for trans-splicing, with the exception of U1 snRNP. The spliced-leader RNA itself along with protein cofactors likely carries out the analogous U1 snRNP function of presenting the 5' splice site to the spliceosome. Again, an adenosine in the outtron upstream of the 3' splice site is the nucleophile for attack in the first step of splicing, although the discontinuous nature of the sequences yield Y-shaped rather than lariat structure. Spliced-leader trans-splicing provides a mechanism to separate individual open reading frames from polycistronic messages that are produced by the host organism and to supply the 5' cap structure required for appropriate translation of mRNA.

Trans-splicing by the spliceosome in other organisms is quite rare. There are a few examples of genes in *Drosophila* with unusual architecture that are resolved by trans-splicing. Included in these examples is the *mod4* gene, which has one exon encoded on the antisense strand that is separately transcribed and joined to the sense transcript by splicing. The *lola* gene shows remarkable trans-splicing between different alleles, such that transcripts from sister chromosomes are joined together. Sporadic reports of other trans-spliced genes have been reported, but it is often not apparent whether these represent biologically programmed events or anomalies of the splicing process.

Another set of well-documented cases of trans-splicing occurs with discontinuous group II introns. For example, the first portion of the intron is located at the end of an RNA gene transcript, while the remaining part of the intron is located at

the beginning of another RNA transcript. These transcripts must come together in order to carry out the splicing reaction, guided in part by base pairing of secondary structural elements of the intron. This type of splicing results in the joining of two exons from separate transcripts. This situation has been found with several organellar genes, and correct splicing is required to generate intact open reading frames for the discontinuous host gene. Given the similarities in splicing mechanism, identity of key nucleotides in the U6 snRNA, and the potential for parts of the group II intron to be expressed in *trans* to the splice sites, a path for evolution of the spliceosome from group II introns has been proposed. Along this path, parts of the group II intron become the snRNAs, which at some point become dependent on proteins for their assembly into a chemically competent catalyst, and eventually introns are fully separated from the splicing machinery.

Evolutionary Implications of Splicing

Data support that self-splicing introns act as progenitors of evolution in that they can behave as mobile genetic elements (thereby creating new genes) and their auto-catalytic activity might be a window back to a world in which RNA alone served as an information repository and carried out the enzymatic functions of life. Although the relationship between the origin of introns and protein-coding genes is not clear, analysis of the increasing number of genome sequences from various organisms indicates that the earliest eukaryotes had introns. A common hypothesis suggests that these arose from mobile group II introns that actively transposed into the genome of the last common eukaryotic ancestor. Indeed, some current group II introns have the ability to retrotranspose using enzymes encoded within the intron.

At first glance, the continued presence of introns in eukaryotic genes begs the question of why these apparently parasitic sequences would be retained through evolution. However, several positive effects have been suggested as possible reasons for introns to be retained and even expanded in the genome. These possibilities include facilitating the creation of new genes by means of rearranging entire exon sequences without disrupting their coding potential. Additionally, splicing provides another point for regulation of gene expression. Alternative splicing appears to be a manifestation of both of these ideas.

Splicing and Human Disease

The spliceosome is charged with two contradictory tasks, in which intron removal must be precise and efficient while still flexible enough to allow for regulation of alternate exon use. Maintaining this balance means that small changes in either sequences in pre-mRNA that direct splicing or the machinery that recognizes these sequences will result in altered gene expression that may result in disease. Several human pathologies are associated with mis-splicing and have been mapped to mutations in *cis*-RNA splicing elements of pre-mRNA or mutations in *trans*-acting factors. Up to 10% of human diseases, the etiology of which is genetic in origin, contain mutations in 5' splice site or 3' splice site consensus sequences.

Examples include atypical cystic fibrosis, neurofibromatosis type 1, and familial dysautonomia. Mutations in sequences that regulate alternative splicing of genes are linked to an increasing number of diseases including cancers, forms of dementia, and Parkinsons. In addition to *cis*-mutation, genetic changes that alter the function of splicing machinery or regulators of alternative splicing are causative for genetic diseases such as retinoblastoma and a range of muscular and neural degenerative diseases. Some examples are spinal muscle atrophy, forms of myotonic dystrophy, and some cerebral ataxias.

If alterations in splicing can cause disease, then it follows that targeting these alterations in patients may yield therapeutic benefits. Indeed, with the disease spinal muscle atrophy, researchers recently reported in a mouse-model the correction of mis-splicing and significant decrease in deleterious symptoms with the introduction of a stable oligonucleotide that targets a mutant regulatory splicing element in the SMN gene. This so-called anti-sense oligotherapy is showing promise in several other splicing disease models. Additionally, a few compounds that target components of the spliceosome or splicing regulators show therapeutic potential. For example, derivatives of a natural product that target a key spliceosome component have been shown to be selectively cytotoxic against a collection of pediatric cancer cell lines. Another promising example is a compound that interferes with the splicing of the HIV transcript. As our understanding of the role of splicing in disease expands, we can expect an increasing arsenal of potential drugs that modulate splicing to mitigate those pathologies.

Summary

When first discovered, introns were suggested to be junk DNA interruptions in protein-coding sequence, and splicing was therefore a chore that cells needed to perform in order to express

their genes. Now we understand that splicing represents an important mechanism for regulating expression of eukaryotic genes. Further exploration of these mechanisms will certainly be important for understanding and intervening in the growing number of human genetic diseases. Looking at the evolution of splicing, it appears that introns likely started as selfish genetic elements that had the surprising ability to self-splice. It has also been suggested that catalytic activity of these introns might be a window back to a world in which RNA was the only enzyme. The study of splicing has opened many fascinating avenues of investigation into molecular biology, evolution, and human health, and one can only hope that the exciting journey will continue.

Glossary

Adipocyte differentiation The process through which adipocyte precursor cells acquire characteristics of mature adipocytes.

Antagomir Antisense oligonucleotide sequence conjugated to cholesterol.

Antisense oligonucleotides Single strands of DNA or RNA that are complementary to a chosen messenger RNA sequence.

Knockdown The reduction of gene expression achieved by certain techniques, such as RNA interference.

Knockout The deletion of gene(s) from the genome of an organism.

β -Cell A type of cell found in the islets of Langerhans in pancreas that produces insulin.

Introduction

Transcriptional regulation of gene expression represents one of several important and fundamental mechanisms governing energy metabolism. There are many different classes of RNAs, one of which is called micro-RNAs (miRNA). miRNAs are small, noncoding RNAs ~19–22 nucleotides in length. They regulate gene expression post-transcriptionally by base-pairing with their cognate target sequences located at the 3'-untranslated regions (3'-UTRs) of protein-coding mRNAs, leading to cleavage or translational inhibition of the target mRNAs. This miRNA-based mechanism of regulating gene expression is evolutionarily conserved from plants to humans. Abundant and ubiquitously expressed, this class of small RNAs has emerged as an important tool kit employed by cells to fine-tune the expression levels of protein-coding genes. As many as 721, 579, and 325 miRNAs have been discovered in the human, mouse, and rat genomes, respectively; annotations of these miRNAs have been deposited in a public miRNA repository database, miRBase. Estimates suggest that ~1–3% of the human and mouse genomes code for miRNA genes, and as much as 30% of the protein-coding genes are regulated by miRNAs in higher eukaryotic species. Therefore, it is not surprising that miRNAs have been shown to play wide-ranging roles in many biological processes, including development, cell differentiation, apoptosis, and immune response. Rapid progress has also been made recently to understand the role of miRNAs in metabolism. Recent studies suggest that miRNAs participate in metabolic processes, including insulin secretion, pancreatic islet cell development, adipocyte differentiation, and insulin signaling, in a variety of tissues. The discovery of miRNAs and their roles in regulating metabolism has added a new dimension to our understanding of the complex metabolic circuitry that governs energy homeostasis.

miRNA Biogenesis

Approximately 720 miRNA coding regions are scattered throughout the human genome. Some miRNA genes exist as independent transcriptional units and are often located in

regions of the genome devoid of protein-coding genes. Other miRNA genes are located in the intronic regions of protein-coding genes. The biogenesis of miRNA starts with transcription initiated by RNA polymerase II or III, generating a long primary miRNA (pri-miRNA) transcript containing a 5'-cap structure and a 3'-poly(A) tail (Figure 1). The complementary region of the pri-miRNA forms a hairpin loop. The loop is recognized by the miRNA processing machinery, composed of Drosha and DGCR8 (DiGeorge syndrome critical region protein 8), which cleaves the structure at the bottom of the stem loop to generate an ~70-nucleotide precursor miRNA (pre-miRNA) transcript. The pre-miRNAs are then exported from the nucleus by the nuclear export machinery (exportin 5 and Ran-GTP). Once in the cytoplasm, the pre-miRNAs are further processed by Dicer, an RNase III-type enzyme, to generate ~22-nucleotide miRNA duplexes. These RNA duplexes are subsequently incorporated into the RNA-induced silencing complex (RISC). One strand of the RNA duplex is discarded while the mature miRNA strand remains in the RISC. The miRNAs then mediate their effects on gene expression by base-pairing with complementary sequences in the 3'-UTR of the target mRNAs, resulting in silencing of the target mRNAs via Argonaute-dependent mRNA cleavage and/or translational repression. Translationally repressed mRNAs are either degraded by the mRNA decay pathway or stored away in a specialized intracellular granule compartment termed the 'P-body'.

miRNA in Pancreatic β -Cell Biology

The evidence for miRNA functions in pancreatic β -cells came from the cloning of small RNAs found in the mouse insulinoma cell line, MIN6. The most abundant miRNA in MIN6 cells is miR-375, which has been shown to negatively regulate glucose-stimulated insulin secretion. Overexpression of miR-375 leads to decreased glucose-stimulated insulin release, while loss of function of miR-375 increases insulin release from pancreatic β -cells. miR-375 regulates insulin secretion partly by repressing the expression of myotrophin (Mtpn), a protein important for intracellular vesicle transport in neurons. Indeed, overexpression of miR-375 in cells decreases the expression of

Figure 1 The biogenesis of miRNA.

Mtpn. miR-375 binds directly to the 3'-UTR region of the Mtpn gene, indicating that Mtpn is a direct target of miR-375. Importantly, knockdown of Mtpn mRNA levels by small interfering RNAs (siRNA) also inhibits glucose-stimulated insulin release, consistent with the inhibitory effect of miR-375 on insulin secretion.

miR-9 also negatively regulates insulin secretion, by repressing the expression of a transcriptional repressor, Onecut2 (OC2). One of the genes repressed by OC2 is the guanosine triphosphatase (GTPase) effector, granuphilin/Slp4. Granuphilin is associated with secretory granules and, upon glucose stimulation, negatively regulates the exocytosis of insulin-containing granules from the β -cells. Therefore, when the expression of OC2 is inhibited by miR-9, the expression levels of granuphilin/Slp4 increase. Increased granuphilin/Slp4 results in decreased glucose-stimulated insulin secretion from the β -cells. Because OC2 is a direct target of miR-9, silencing OC2 expression by RNAi mimics the effects of miR-9 on the expression of granuphilin/Slp4 and insulin-containing granules exocytosis.

miRNAs also play a role in the development and proliferation of insulin-producing pancreatic β -cells. For example, miR-124a is abundantly expressed in β -cells and inhibits β -cell development. It acts by targeting Foxa2, a critical transcription factor that regulates β -cell development. Overexpression of miR-124a inhibits the expression of Foxa2 and other essential genes (e.g., Pdx-1, Kir6.2, and Sur-1) involved in β -cell development and function. Knockdown of miR-124a levels in cells abolishes the inhibitory effects on Foxa2 and other targets. In contrast to miR-124, miR-375 positively promotes the development and/or proliferation of β -cells. Mice in which the miR-375 gene has been ablated show significant increases in the numbers of glucagon-producing α -cells, and a decrease in

the numbers of insulin-producing β -cells in their pancreatic islets. These studies support a role for miR-375 in regulating different endocrine cell types in the pancreas.

miRNA in Lipid Metabolism

A study demonstrating how a specific miRNA, miR-14, regulates lipid metabolism in the fruit fly, *Drosophila melanogaster*, first implicated miRNAs in this process. miR-14 negatively regulates intracellular triglyceride levels in the fat body (analogous to mammalian adipose tissue) of *Drosophila*. Ablating the miR-14 gene in *Drosophila* increases triacylglycerol and diacylglycerol levels; however, increasing miR-14 expression lowers these levels. Similarly, miR-278 has been shown to regulate fat body metabolism in *Drosophila*. Loss of function of miR-278 results in decreased fat body size and a corresponding reduction in whole-body triglyceride-to-protein ratio in flies. Interestingly, miR-278-deficient flies also suffer from hyperglycemia despite increased levels of insulin-like peptide, suggesting the presence of insulin resistance in these flies.

Although mammals do not have the equivalent of *Drosophila* miR-14 or miR-278, miRNAs are involved in regulating mammalian lipid metabolism. For example, miR-143 promotes adipogenesis. The expression of miR-143 increases during the course of adipogenesis in tissue culture, as well as in mice. Knockdown of miR-143 levels in human preadipocytes by antisense oligonucleotides causes a significant decrease in adipocyte differentiation. Conversely, overexpression of miR-143 in murine 3T3-L1 preadipocytes accelerates differentiation into mature adipocytes. Similarly, miR-103 promotes adipocyte differentiation. Overexpressing miR-103 in 3T3-L1

preadipocytes leads to increased expression of many adipocyte-specific markers, such as peroxisome proliferator-activated receptor- γ (PPAR- γ) and fatty acid binding protein 4 (FABP4), concurrent with an early increase in triglyceride accumulation during the course of adipocyte differentiation in culture. Two additional miRNA families, miR-200 and miR-17-92, also positively regulate the process of adipocyte development. Overexpression of the miR-200 or miR-17-92 clusters accelerates the conversion of mouse ST2 marrow stromal cells or 3T3-L1 fibroblasts into mature adipocytes, respectively. In contrast, one particular miRNA, miR-27, opposes adipocyte differentiation by targeting and inhibiting the expression of two key transcription factors that drive adipogenesis, PPAR- γ and CCAAT/enhancer binding protein- α (C/EBP- α). These recent studies highlight the intersection of transcription- and miRNA-based mechanisms in controlling adipocyte differentiation.

Unlike in adipocytes, liver miRNA expression is dominated by a single miRNA, miR-122, which exists in $\sim 50\,000$ copies per cell. Abolishment of miR-122 expression in mice using antisense oligonucleotides conjugated to cholesterol (called antagomirs) results in the lowering of plasma cholesterol levels. This effect is mediated, in part, by the miR-122-dependent repression of cholesterol biosynthetic genes in liver, such as the HMG-CoA reductase. A second study, using a similar knockdown approach against miR-122, demonstrated a reduction in fatty acid synthesis and an increase in fatty acid oxidation in primary hepatocytes. These metabolic alterations are accompanied by an increase in adenosine monophosphate (AMP)-activated kinase (AMPK) levels, consistent with the known function of AMPK in promoting fatty acid oxidation while inhibiting fatty acid synthesis in liver.

miRNA in Glucose Metabolism and Insulin Signaling

miRNAs can not only regulate glucose metabolism by affecting the magnitude of insulin secretion from pancreatic β -cells, but also modulate insulin signaling and action in insulin-responsive tissues. Studies comparing miRNA expression profiles in healthy versus type 2 diabetic rats identified two miR-29 family members, miR-29a and miR-29b, that are upregulated in muscle, adipose, and liver of diabetic animals. Overexpression of miR-29 in 3T3-L1 adipocytes suppresses insulin-stimulated glucose uptake, an effect likely due to inhibition of protein kinase B/Akt activation. Consistent with its upregulation in diabetic animals, miR-29 expression is also increased in adipocytes cultured in high glucose and high insulin-containing media. This observation suggests a possible involvement of miR-29 in the development of insulin resistance; however, the mechanism behind the role of miR-29 in insulin resistance is not known. Although insulin-induced gene 1 (Insig1) and caveolin 2 (Cav2) were identified as miR-29 targets, their roles in insulin signaling and glucose metabolism remain to be clarified.

Other miRNAs are also implicated in controlling the insulin receptor signaling pathway. However, the direct effects of these miRNAs on glucose metabolism remain to be established. For example, miR-145 can directly target and suppress the expression of insulin receptor substrate 1 (IRS1), a key component of the insulin receptor signaling pathway. Overexpression of miR-145 in colon cancer cells leads to growth arrest, a

phenotype reminiscent of IRS1 knockdown by siRNA in these cells. Another miRNA cluster, miR-183-96-182, targets multiple components of the insulin receptor signaling pathway, including IRS1, Rasa1, and Grb2. These observations suggest that for a given signaling pathway, multiple miRNAs can target different components of the signaling cascade, effectively shutting it off.

miRNA in the Treatment of Metabolic Diseases

The implication of specific miRNAs in metabolic diseases (e.g., miR-29 in diabetes) has raised the hope that targeting these miRNAs may be a viable therapeutic approach to treat metabolic disorders. Various methods and tools are now available to modulate the expression of specific miRNAs *in vivo*. A gain of function can be achieved *in vivo* using viral-based methods to overexpress a synthetic form of any given miRNA in a desired tissue. A loss of function can be achieved *in vivo* by the delivery of antisense oligonucleotides specific to a target miRNA. In general, these antisense oligonucleotides are chemically modified to increase their stability and binding specificity. Several proof-of-principle studies have successfully demonstrated the feasibility and effectiveness of using adenovirus and lentivirus to deliver miRNA genes in mice. In addition to viral-based strategies, synthetic RNAs (e.g., antisense oligonucleotides) can be successfully delivered to tissues *in vivo* by conjugating synthetic RNAs to cholesterol and encapsulating them within the high- or low-density lipoproteins. However, this approach is limited because the encapsulated synthetic RNAs can be best delivered to only a few tissues such as the liver, intestine, and kidney. Perhaps a bigger problem with targeting miRNA to treat diseases lies in the specificity of the miRNA therapy. First, one miRNA can target several distinct genes and one gene can be targeted by multiple distinct miRNAs. It is not desirable to suppress those miRNAs that are not directly involved in disease pathogenesis. Thus, the potential off-target effects pose a significant challenge to miRNA-based therapy. Second, most of the miRNAs exhibit spatial, temporal, and tissue-specific expression patterns, characteristics necessary to their proper function. Therefore, a generic overexpression of miRNAs may not achieve the desired therapeutic effects. Whether miRNA-based therapeutic agents can be successfully deployed to treat metabolic diseases in clinical settings remains an open question.

Conclusion

miRNAs comprise a diverse family of small noncoding RNAs that play important roles in fine-tuning gene expression and have been implicated in many fundamental physiologic processes. The roles of miRNA in metabolism (Table 1) are still being uncovered, and many miRNAs potentially important to this process are yet to be characterized. The immediate goals in the miRNA community are to validate the authenticity of the predicted miRNA genes *in vivo* and to clone new miRNA genes, establish their function, and identify their mRNA targets. While miRNA-based therapy is an attractive alternative to treat certain metabolic diseases, the questionable specificity of

Table 1 The role of miRNAs in metabolism

miRNA	Metabolic regulation	Target tissues/cell lines	Target genes
miR375	Insulin secretion; α - and β -cell proliferation; β -cell development	Pancreas	Mtpn, Usp1
miR9	Insulin secretion	Pancreas	OC2
miR-124a	Development and proliferation of β -cell	Pancreas	Foxa2, Rab27A
miR-14	Lipid metabolism in fat body	Fat body (<i>Drosophila</i>)	Unknown
miR-278	Lipid metabolism in fat body; insulin resistance	Fat body (<i>Drosophila</i>)	Expanded
miR-143	Adipogenesis	Human preadipocytes; 3T3-L1 cells	ERK5/MAPK7
miR-103	Adipogenesis	3T3-L1	Unknown
miR-200	Adipogenesis	Mouse ST2 cells	Unknown
miR-17-92	Adipogenesis	3T3-L1 cells	Rb2/p130
miR-27	Adipogenesis	3T3-L1 cells	PPAR- γ and C/EBP- α
miR-122	Cholesterol and fatty acid metabolism	Liver	HMG-CoA reductase
miR-29	Diabetes, insulin resistance	Muscle, adipose, and liver	Insig1 and Cav2
miR-145	Insulin signaling; growth	Colon cancer cells	IRS1
miR-183-96-182	Insulin signaling		IRS1, Rasa1, and Grb2

miRNA-based therapy and the challenge of delivering miRNA or anti-miRNA molecules to the desired target tissues *in vivo* will be the key issues that need to be addressed in the near future.

Glossary

Ca²⁺-release channel A channel that releases Ca²⁺, when opened, from an intracellular organelle, commonly from the sarcoplasmic reticulum in muscle and the endoplasmic reticulum in other tissues. The Ca²⁺-release channel is a 2200-kDa complex consisting of four large and four small subunits.

Excitation–contraction (EC) coupling A mechanism that refers to the conversion of an electrical stimulus into a cellular response. In muscle, the electrical stimulus

is usually an action potential and the mechanical response is contraction.

FK506 binding protein (FKBP) It is a 12-kDa immunophilin and subunit of the ryanodine receptors, also referred to as 'calstabin'.

Ryanodine receptor Ca²⁺ channel that binds with high affinity the plant alkaloid ryanodine. Ryanodine opens the Ca²⁺ channel at nanomolar concentrations and closes the channel at micromolar concentrations.

Distribution, Isolation, and Structure of RyRs

RyRs have been characterized in a variety of nonvertebrate and vertebrate species, including flies, crustaceans, birds, and amphibians. In mammals, there are three widely expressed RyR isoforms. RyR1 is the dominant isoform in skeletal muscle. RyR2 is found in high levels in cardiac muscle. RyR3 was initially identified in the brain but is expressed in many tissues including smooth muscle and brain.

The mechanism of RyR ion channel function has been most extensively studied in striated muscles. In skeletal and cardiac muscle, an action potential triggers the intracellular release of Ca²⁺ by a mechanism referred to as 'excitation–contraction (EC)' coupling. The two major membrane structures involved in EC coupling are transverse (T-) tubule membrane system of invaginations (and plasmalemma in myocardium) and intracellular Ca²⁺-storing and Ca²⁺-releasing organelle, the sarcoplasmic reticulum (SR), which contains an adenosine triphosphate (ATP)-dependent Ca²⁺ pump (SERCA) and Ca²⁺-release channel. The release channels typically span the narrow gap where the SR and T-tubule (and plasmalemma) are within ~15 nm of each other. The SR Ca²⁺-release channels are also known as 'feet' or 'junctional processes', and as 'ryanodine receptors' (RyRs) to distinguish them from other intracellular Ca²⁺ channels. The plant alkaloid ryanodine binds with high affinity and specificity to RyRs and modifies their single-channel conductance in a highly characteristic way by inducing a long-lasting subconductance state at low concentrations and closed channels at elevated concentrations.

In mammalian skeletal muscle, an action potential initiates L-type Ca²⁺ channel (Ca_v1.1) protein conformational changes that alter the conformation of closely apposed RyR1s by a direct physical interaction. In cardiac muscle, an action potential results in the influx of extracellular Ca²⁺ through Ca_v1.2 channels. Both mechanisms lead to the release of Ca²⁺ from the SR and subsequent muscle contraction. Sequestration of released Ca²⁺ by the SR Ca²⁺-transporting adenosine triphosphatase (ATPase) (SERCA) and extrusion by the Na⁺–Ca²⁺

exchanger restore the myofibrillar Ca²⁺ concentration from 10^{–6}–10^{–5} to ~10^{–7} M, causing muscle to relax.

The mammalian RyRs share ~70% sequence homology, with the greatest homology in the carboxyl-terminal region. In all isoforms, the C-terminal portion of the protein contains the transmembrane domain. Hydropathy analysis suggests between four and 12 transmembrane segments per RyR subunit. More recent studies suggest that six membrane-spanning segments per RyR subunit are sufficient to form a channel. The remaining RyR amino acids form the large catalytic cytoplasmic foot structure. Experimental information on the structure of the RyRs has been mainly obtained by cryo-electron microscopy. Three-dimensional reconstruction of electron micrographs of frozen-hydrated RyR specimen shows dimensions of 29 × 29 × 12 nm for the large cytoplasmic assembly with a 7-nm length and 8-nm diameter for the transmembrane domain (Figure 1). Cryo-electron microscopy reveals conformational changes that accompany channel opening, shows the location of various effectors on the large RyRs, and provides evidence that the transmembrane region of RyR1 has a pore structure similar to the K⁺ channels.

The large size facilitates isolation of functional RyRs. Good results are obtained using SR vesicle preparations highly enriched in RyRs such as those isolated from rabbit skeletal muscle. SR vesicles are solubilized using the detergent CHAPS and RyR1s are purified in one step as 30 S complexes by sucrose density gradient rate centrifugation.

RyR1 Pore Structure

RyRs have large conductances for both monovalent (~750 pS with 250 mM K⁺) and divalent (~150 pS with 50 mM Ca²⁺) cations, while maintaining divalent versus monovalent selectivity (P_{Ca}/P_K~7). Sequence comparison, cryo-electron microscopy, and extensive mutagenesis, and single channel studies indicate that the RyRs have a pore structure similar to that of K⁺ channels whose structure is known (Figure 2). In the

RyRs, the residues between the two C-terminal membrane-spanning segments are lumenally located and have a pore helix and an amino acid motif (GGGIG) that is similar to the selectivity filter motif (TV/IGYG) of K^+ channels. Mutagenesis shows that rings of negative charges in the luminal and cytosolic vestibules maintain the high rates of RyR1 ion fluxes. Several models of RyR ion permeation based on Eyring rate theory, Poisson–Nernst–Planck-density functional theory, and the solution structure of K^+ channels have been described.

Regulation by Ca^{2+} and Endogenous Effectors

The *in vitro* function of RyR ion channels has been primarily studied by measurement of (1) Ca^{2+} fluxes from SR vesicles, (2) single channels incorporated in planar lipid bilayers, and (3) [3H]ryanodine binding. These studies have shown that RyRs are Ca^{2+} -gated channels that are activated by micromolar

Figure 1 Three-dimensional reconstruction of RyR1. The cytoplasmic (green) and transmembrane (pink) domains are shown. Scale bar, 10 nm. Reproduced from Samso M and Wagenknecht T (1997) Contributions of electron microscopy and single-particle techniques to the determination of the ryanodine receptor three-dimensional structure. *Journal of Structural Biology* 121: 172–180, with permission from Academic Press.

Ca^{2+} concentrations and inhibited by millimolar Ca^{2+} concentrations. Mg^{2+} inhibits RyRs by binding to high-affinity and low-affinity Ca^{2+} -binding sites. ATP complexed with Mg^{2+} modifies regulation of RyRs by Ca^{2+} indicating that it is an allosteric modulator of Ca^{2+} -gated RyR activity. Similarly, monovalent cations and anions affect Ca^{2+} -gated channel activity by binding to specific regulatory sites. In addition to cytosolic Ca^{2+} , SR luminal Ca^{2+} regulates RyRs at several channel sites. Ca^{2+} binds to luminal channel sites and by passing through the channel accesses cytosolic Ca^{2+} activation and inactivation sites.

RyRs and Calmodulin

Calmodulin (CaM) is a small, cytoplasmic Ca^{2+} -binding protein that regulates cellular activities including protein kinases and ion channels. A notable property of the RyRs is their direct interaction with CaM in the absence and presence of Ca^{2+} . Ca^{2+} -free and Ca^{2+} -bound forms of CaM bind to a highly conserved CaM-binding domain of RyRs. Cryo-electron microscopy indicates that Ca^{2+} -free and Ca^{2+} -bound forms of CaM bind to an overlapping region distal to the effector site (ion pore). This suggests that CaM exerts its effects allosterically over relatively long-range interactions within the RyRs. CaM inhibits the three mammalian RyR isoforms at micromolar Ca^{2+} concentrations. At submicromolar Ca^{2+} concentrations, RyR2 is also inhibited by CaM but RyR1 and RyR3 are activated to different extents by CaM. Site-directed mutagenesis in CaM-binding domain alters CaM binding and regulation to different extents, which suggests that other RyR type-specific sites are involved in transducing CaM binding into functional effects.

Crystal structure analysis of the complex between the Ca^{2+} -bound form of CaM and peptide corresponding to the CaM-binding domain of RyR1 (p3614–3643) reveals an interaction

Figure 2 All-atom pore model of RyR1. Two of the four subunits are shown in cartoon representation. Residues whose mutation affects channel function are shown in stick representation. From Ramachandran S, Serohijos AWR, Xu L, Meissner G, and Dokholyan NV (2009) A structural model of the pore-forming region of the skeletal muscle ryanodine receptor (RyR1). *PLoS Computational Biology* 5: 1–10.

of the C-terminal and N-terminal domains of CaM with two hydrophobic anchor residues, W3620 and F3636, respectively, at a novel 1–17 spacing. Nuclear magnetic resonance (NMR) and fluorescence resonance energy transfer (FRET) measurements indicate that the C-terminal domain of CaCaM tightly binds to the N-terminal end of the peptide, and furthermore show that in the complex each domain can interact independently with its own half of the peptide.

Expression of RyR1 mutant deficient in the regulation by CaM in mice suggests that CaM has a modest role in *in vivo* regulation of RyR1. By contrast, CaM inhibition of RyR2 is required for normal cardiac function. Mice with point mutations in the CaM-binding domain of the cardiac ryanodine receptor ion channel have large hearts and die at an early age. Sustained Ca^{2+} transients reveal an abnormal Ca^{2+} handling in homozygous mutant cardiomyocytes.

RyRs and Protein Kinases

Primary sequence analysis suggests the presence of many phosphorylation sites in the large cytoplasmic foot region of the RyRs. Kinases and phosphatases that are part of the RyR1 and RyR2 multiprotein complexes include protein kinase A (PKA), Ca^{2+} /CaM-dependent protein kinase II (CaMKII), and protein phosphatase 1 and protein phosphatase 2A (PP2A). RyR1 has been reported to be phosphorylated at Ser2843. RyR2 is phosphorylated at Ser-2030 by PKA, Ser-2809 by PKA, and CaMKII (corresponding to Ser2843 in RyR1) and Ser-2815 by CaMKII. However, there is evidence for additional phosphorylation sites in RyR1 and RyR2. Phosphorylation of RyRs by protein kinases has been suggested to result in leaky SR Ca^{2+} channels (see below).

RyRs and Reactive Oxygen and Nitrogen Species

The tetrameric mammalian skeletal and cardiac RyRs have 404 and 364 cysteines, with 100 and 89 cysteines per 560 kD subunit, and one and two per FK506-binding protein, respectively. Nearly half of the 404 cysteines in the tetrameric RyR1 channel complex are free in the presence of 5 mM reduced glutathione (GSH) at $\text{pO}_2 \sim 10$ mm Hg, that is, under conditions that simulate pO_2 and glutathione redox state. An increase in oxygen tension from ~ 10 mm Hg to ambient air ($\text{pO}_2 \sim 150$ mm Hg) results in loss of 6–8 free thiols/RyR1 subunit without appreciably changing RyR1 activity. Substitution of GSH with oxidized glutathione (GSSG) at $\text{pO}_2 \sim 10$ mm Hg or ambient air reduces the number of free thiols/RyR1 subunit and results in a large increase in RyR1 activity. RyR2s also have functional thiols that respond to the cells' pO_2 and GSH/GSSG redox state. Regulation of RyR1 by SepN1, a selenoprotein, and RyR1 and RyR2 by plasmalemmal- and SR-associated NAD(P)H oxidases has been described.

Both RyR1 and RyR2 are endogenously S-nitrosylated, suggesting that NO or NO-related species are physiological modulators of skeletal and cardiac muscle EC coupling. Although in normal skeletal and cardiac muscle, the predominant skeletal (nNOS) and cardiac (eNOS) nitric oxide isoforms are targeted to the plasmalemma, a specific association of nNOS

with RyR2 has been described. This suggests that eNOS and nNOS have specific roles in mediating S-nitrosylation and regulation of plasmalemmal $\text{Ca}_v1.2$ and RyR2, respectively.

In *in vitro* studies, NO and NO-related species activate or inhibit RyRs depending on donor concentration, membrane potential, the presence of channel agonists, and other sulfhydryl-modifying reagents. RyR1 is S-nitrosylated and activated by low physiological concentrations of NO at tissue pO_2 (~ 10 mm Hg) but not at ambient air ($\text{pO}_2 \sim 150$ mm Hg). This suggests that RyR1 is an O_2 and NO-sensing molecule. Like RyR1, RyR2 activity is dependent on pO_2 . However, RyR2 is not effectively activated and S-nitrosylated by NO *in vitro*, although it is activated by other endogenous NO-related species.

A number of reactive thiols have been identified. 7-Diethylamino-3-(4'-maleimidylphenyl)-4-methylcoumarin (CPM) selectively labels seven hyperreactive RyR1 cysteines (Cys-1040, 1303, 2436, 2565, 2606, 2611, and 3635). In another study, nine RyR1 cysteines (Cys-36, 315, 811, 906, 1591, 2326, 2363, 3193, and 3635) are endogenously modified and another three (Cys-253, 1040, and 1303) are modified by exogenous reactive oxygen and nitrogen molecules. RyR1-Cys3635 is specifically S-nitrosylated by NO at low, physiological O_2 concentrations.

Pharmacology of RyRs

The RyRs constitute a rich pharmacological target for controlling SR Ca^{2+} release. Exogenous effectors found to affect RyR function include ryanoids, toxins, caffeine, and other xanthines, anthraquinones, phenol derivatives, dantrolene, local anesthetics, and polycationic and sulfhydryl-reacting reagents.

RyR-Associated Proteins

A large number of junctional SR membrane proteins and cytosolic and SR luminal proteins have been reported to form a macromolecular complex with the RyRs and to modulate their activity. These include kinases, phosphatases, CaM (see above), S100A1, triadin, junctin, JP-45, junctate, juncophilin, homer, sorcin, and calsequestrin.

RyRs and Muscle Disorders

Mutations in RyR1 give rise to muscle diseases, malignant hyperthermia (MH), central core disease (CCD), and multi-minicore disease (MmD). MH is an inherited disease that causes a rapid rise in body temperature and muscle contraction when the affected person receives general anesthesia. MH-linked mutations were initially mapped to hot spots within the NH_2 and central domains; however, more recently identified MH mutations appear to be distributed throughout the entire RyR1 coding sequences including the C00H-terminal domain of the channel. CCD and MmD are congenital diseases associated with a dysfunctional RyR1. In many cases, dominant RyR1 mutations linked to CCD localize to the COOH-terminal domain of the channel. Single-channel measurements

indicate that CCD mutants lose the ability to conduct Ca^{2+} . A CCD mutation in the selectivity filter of RyR1 (I4897T) (Figure 2) provided early evidence regarding the pore structure of the RyRs. Crystal structure of the N-terminal domain has identified the location of several disease-associated mutations in RyR1 and RyR2.

In humans, RyR2 mutations are associated with catecholaminergic polymorphic ventricular tachycardia and arrhythmogenic right ventricular cardiomyopathy. A deficiency in SR luminal cardiac calsequestrin and missense mutation D307H also result in imbalances of Ca^{2+} handling and catecholaminergic polymorphic ventricular tachycardia. Overexpression of CSQ2 results in suppressed SR Ca^{2+} transients and severe cardiac hypertrophy in mice. Abnormal Ca^{2+} handling is also observed in mice that lack or overexpress RyR-associated proteins, triadin, and junctin.

Sustained stimuli associated with stress can lead to maladaptive changes of β -adrenergic receptor signaling, cardiomyocyte death, and heart failure. In failing hearts, RyR2 has been reported to be PKA hyperphosphorylated, depleted of the FKBP12.6 subunit, and to exhibit increased channel activity. Similarly, in skeletal muscle of animal models with heart failure and patients with heart diseases, exercise is linked to hyperphosphorylation and FKBP12 depletion of the skeletal muscle RyR1, increased RyR1 channel activity, and decreased exercise capacity. These findings led Marks and colleagues to propose that PKA hyperphosphorylation and dissociation of the small FKBP subunit from the RyRs result in increased RyR sensitivity to cytosolic Ca^{2+} , referred to as leaky SR Ca^{2+} channels. However, other laboratories have failed to confirm this. More recent studies indicate that CaMKII-mediated RyR2 phosphorylation also results in the formation of leaky SR Ca^{2+} channels.

The small 12- and 12.6-kDa FK506-binding proteins are predominantly associated with RyR1 and RyR2, respectively. They belong to the family of immunophilins, exhibit *cis/trans*-isomerase activity, and their removal is reported to functionally uncouple groups of channels and increase channel activity. Mechanisms implicated in generation of dysfunctional release channels include PKA-mediated phosphorylation, increased S-nitrosylation, oxidation, and loss of PP1, PPA2, and phosphodiesterase 4D from the RyR macromolecular complexes. A 1,4-benzothiazepine derivative, JTV519 (also known as K201), and the more specific derivative S107, have been reported to improve muscle function by stabilizing the RyR–FKBP complex. To define the specificity of RyR1 and RyR2 phosphorylation, mutants were prepared that mimic the dephosphorylated (alanine) or phosphorylated (aspartic acid) forms. In some studies, Ser to Asp substitution increases open channel probability (P_o) and decreases FKBP-binding affinity, whereas mutants with a Ser to Ala substitution exhibit a behavior similar to wild type. In other studies, neither substitution alters channel behavior.

Glossary

Alzheimer's disease (AD) A disease first described by Alois Alzheimer in 1906 characterized by progressive loss of memory and cognition. AD afflicts a major proportion of our aging population and is one of the most serious diseases facing our society today, especially in light of increasing human longevity. The secretases represent important potential therapeutic intervention points in AD treatment.

Proteinases Enzymes that hydrolyze, or split, peptide bonds in protein substrates; they are also referred to as proteolytic enzymes.

Secretase A proteinase identified with respect to its hydrolysis of peptide bonds within a region of a type I integral membrane protein called APP. These cleavages are responsible for liberation, or destruction, of an amyloidogenic peptide of about 40 amino acid residues in length called A β .

β -Amyloid (A β) (The peptide produced from amyloid precursor protein (APP) by the action of β - and γ -secretases. A β shows neurotoxic activity and aggregates to form insoluble deposits seen in the brains of Alzheimer's disease (AD) patients. The α -secretase hydrolyzes a bond within the A β region and releases fragments which do not aggregate.

Secretases are proteolytic enzymes involved in the processing of an integral membrane protein known as amyloid precursor protein, or APP. β -Amyloid (A β) is a neurotoxic and highly aggregative peptide that is excised from APP by secretase action, and that accumulates in the neuritic plaque found in the brains of Alzheimer's disease (AD) patients. The amyloid hypothesis holds that the neuronal dysfunction and clinical manifestation of AD are a consequence of the long-term deposition and accumulation of A β , and that this peptide of 40–42 amino acids is a causative agent of AD. Accordingly, the secretases involved in the liberation, or destruction, of A β are of enormous interest as therapeutic intervention points toward treatment of this dreaded disease.

Background

Proteolytic enzymes play crucial roles in a wide variety of normal and pathological processes in which they display a high order of selectivity for their substrate(s) and the specific peptide bonds hydrolyzed therein. This article concerns secretases, the membrane-associated proteinases that produce, or prevent the formation of, a highly aggregative and toxic peptide called β -amyloid (A β). This A β peptide is removed from a widely distributed and little understood type I integral membrane protein called APP. The apparent causal relationship

between A β and AD has fueled an intense interest in the secretases responsible for its production. Here, we discuss the current understanding of three of the most-studied secretases, α -, β -, and γ -secretases. A schematic representation of the A β region of APP showing the amino acid sequence of A β and the major sites of cleavage for these three secretases is given in [Figure 1](#). A β is produced by the action of β - and γ -secretases, and there is an intense search underway for inhibitors of these enzymes that might serve as drugs in the treatment of AD. The α -secretase cleaves at a site near the middle of A β , and gives rise to fragments of A β that lack the potential for aggregation; therefore, amplification of α -secretase activity might be seen as another approach to AD therapy.

α -Secretase

The activity responsible for cleavage of the Lys¹⁶–Leu¹⁷ bond within the A β region ([Figure 1](#)) is ascribed to α -secretase. This action prevents formation of the 40–42-amino-acid residue A β and leads to release of soluble APP α and the membrane-bound C83-terminal fragment. α -Secretase competes with β -secretase for the APP substrate, but the α -secretase product, soluble APP α (pathway A, [Figure 1](#)), is generated at a level about 20 times that of the sAPP β released by β -secretase (pathway B). Because α -secretase action prevents the

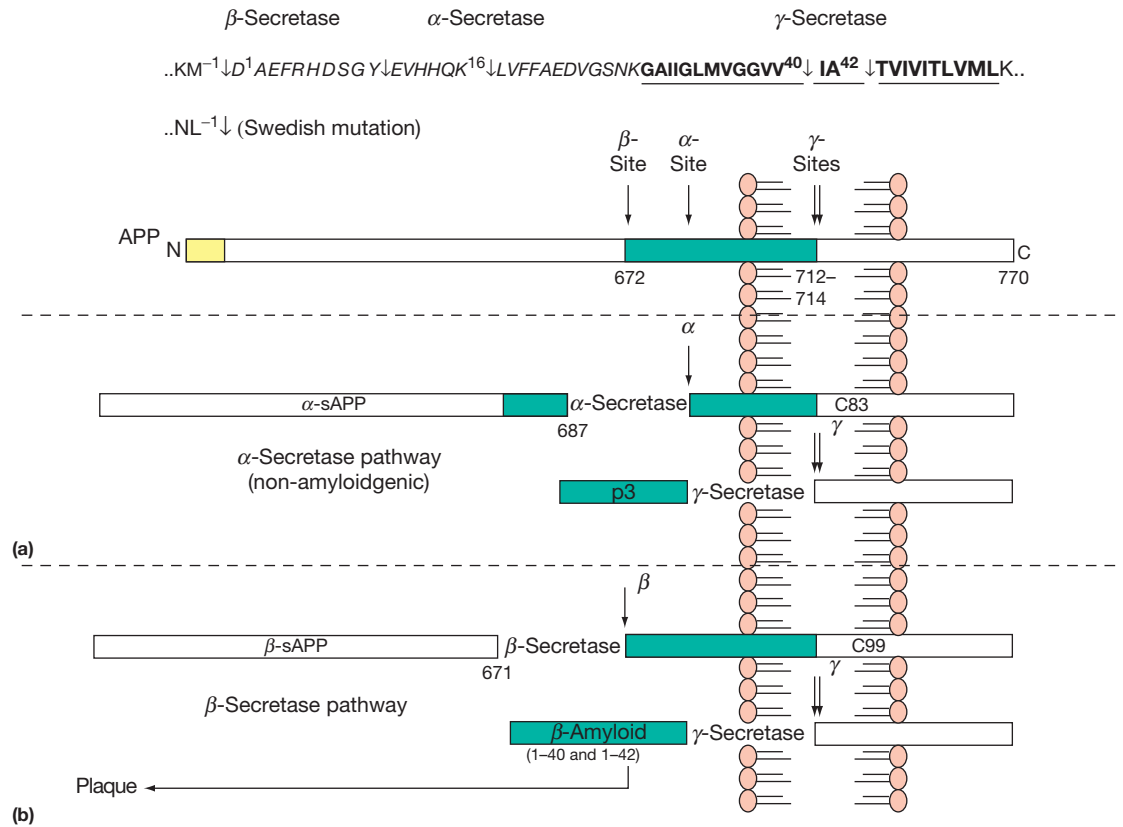

Figure 1 A schematic overview of APP processing by the α -, β -, and γ -secretases. The top panel shows the amino acid sequence of APP upstream of the transmembrane segment (underlined, bold), and encompassing the sequences of A β ₁₋₄₀ and A β ₁₋₄₂ (D¹-V⁴⁰, and D¹-A⁴², respectively). The β -secretase cleaves at D¹ and Y¹⁰; the α -secretase at Lys¹⁶, and the γ -secretase at Val⁴⁰ and/or Ala⁴². Below the sequence is a representation of APP emphasizing its membrane localization and the residue numbers of interest in β - and γ -secretase processing. (a) The non-amyloidogenic α -secretase pathway in which sAPP α and C83 are generated. Subsequent hydrolysis by the γ -secretase produces a p3 peptide that does not form amyloid deposits. (b) The amyloidogenic pathway in which cleavage of APP by the β -secretase to liberate sAPP β and C99 is followed by γ -secretase processing to release β -amyloid peptides (A β ₁₋₄₀ and A β ₁₋₄₂) found in plaque deposits.

formation of the toxic A β peptide, augmentation of this activity could represent a useful strategy in AD treatment, and this has been done experimentally by activators of protein kinase C (PKC) such as phorbol esters and by muscarinic agonists. The specificity of the α -secretase for the Lys¹⁶-↓-Leu¹⁷ cleavage site (Figure 1) appears to be governed by spatial and structural requirements that this bond exists in a local α -helical conformation and be within 12 or 13 amino acids distance from the membrane. α -Secretase has not been identified as any single proteinase, but two members of the ADAM family, ADAM-10 and ADAM-17, are candidate α -secretases (ADAM, a disintegrin and metalloprotease). ADAM-17 is known as a tumor necrosis factor- α -converting enzyme (TACE), and TACE cleaves peptides modeled after the α -secretase site at the Lys¹⁶-↓-Leu position. This was also shown to be the case for ADAM-10; overexpression of this enzyme in a human cell line led to several-fold increase in both basal and PKC-inducible α -secretase activity. As of now, it remains to be proved whether α -secretase activity derives from either or both of these ADAM family metalloproteinases, or whether another as-yet unidentified proteinase carries out this processing of APP.

β -Secretase

The enzyme responsible for cleaving at the amino-terminus of A β is β -secretase (Figure 1). In the mid-1980s, when A β was recognized as a principal component of AD neuritic plaque, an intense search was begun to identify the β -secretase. Finally, in 1999, several independent laboratories published evidence demonstrating that β -secretase is a unique member of the pepsin family of aspartyl proteinases. This structural relationship to a well-characterized and mechanistically defined class of proteases gave enormous impetus to research on β -secretase. The preproenzyme consists of 501 amino acids, with a 21-residue signal peptide, a prosegment of about 39 residues, the catalytic bilobal unit with active site aspartyl residues at positions 93 and 289, a 27-residue transmembrane region, and a 21-residue C-terminal domain. The membrane localization of β -secretase makes it unique among mammalian aspartyl proteases described to date. Another interesting feature of the enzyme is that, unlike pepsin, renin, cathepsin D, and other prototypic members of the aspartyl proteases, it does not appear to require removal of the prosegment as a means of

activation. A furin-like activity is responsible for cleavage in the sequence Arg-Leu-Pro-Arg-↓-Glu²⁵ of the proenzyme, but this does not lead to any remarkable enhancement of activity, at least as is seen in recombinant constructs of pro- β -secretase. β -Secretase has been referred to by a number of designations in the literature, but the term β -site APP cleaving enzyme (BACE) has become most widely adopted. With the discovery of the β -secretase, it was recognized that there was another human homolog of BACE with a transmembrane segment and this has now come to be called BACE2. This may well be a misnomer, as the function of BACE2 is yet to be established, and it is not clear that APP is a normal substrate of this enzyme. At present, BACE2 is not considered to be a secretase.

There is considerable experimental support for the assertion that BACE is, in fact, the β -secretase involved in APP processing. The enzyme is highly expressed in brain, but is also found in other tissues, thus explaining the fact that many cell types can process A β . The use of antisense oligonucleotides to block expression of BACE greatly diminishes production of A β and, conversely, overexpression of BACE in a number of cell lines leads to enhanced A β production. BACE knockout mice show no adverse phenotype, but have dramatically reduced levels of A β . This demonstrates not only that BACE is the true β -site APP processor, but also that its elimination does not pose serious consequences for the animal, a factor of great importance in targeting BACE for inhibition in AD therapy.

Much of the evidence in support of the amyloid hypothesis comes from the observation of mutations near the β - and γ -cleavage sites in APP that influence the production of A β and correlate directly with the onset of AD. One such mutation in APP, which invariably leads to AD in later life, occurs at the β -cleavage site where Lys-Met⁻¹ is changed to Asn-Leu⁻¹ (Figure 1). This so-called Swedish mutation greatly enhances the production of A β , and, as would be expected, β -secretase hydrolyzes the mutated Leu-Asp¹ bond in model peptides ~50 times faster than the wild-type Met-Asp¹ bond. It is important to recognize that BACE cleavage is required for subsequent processing by the γ -secretase; in this sense, a BACE inhibitor will also block γ -secretase. Another BACE cleavage point is indicated in Figure 1 by the arrow at Y¹⁰↓E¹¹; the A β ₁₁₋₄₀ or ₄₂ subsequently liberated by γ -secretase action also forms amyloid deposits and is found in neuritic plaque.

In all respects, therefore, BACE fits the picture expected of β -secretase, and because of its detailed level of characterization and its primary role in A β production, it has become a major target for development of inhibitors as drugs to treat AD. Great strides in this direction have become possible because of the availability of three-dimensional (3-D) structural information on BACE. The crystal structure of BACE complexed with an inhibitor is represented schematically in Figure 2. Homology with the pepsin-like aspartyl proteases is reflected in the similar folding pattern of BACE, with extensive β -sheet organization, and the proximal location of the two aspartyl residues that comprise the catalytic machine for peptide bond cleavage. The C-terminal lobe of the molecule is larger than is customarily seen in the aspartyl proteases, and contains extra elements of structure with as-yet unexplained impact on function. In fact, before the crystal structure was solved, it was thought that this larger C-terminal region might contribute a spacer to distance the catalytic unit from the

Figure 2 Schematic representation of the 3-D structure of the BACE (β -secretase) catalytic unit as determined by X-ray crystallography. Arrows and ribbons designate β -strands and α -helices, respectively. An inhibitor is shown bound in the cleft defined by the amino- (left) and carboxyl- (right) terminal halves of the molecule. The C-terminus of the catalytic unit is marked C to indicate the amino acid residue immediately preceding the transmembrane and cytoplasmic domains of BACE. These latter domains were omitted from the construct that was solved crystallographically. The arrow marks a disulfide bridge, which maintains the C-terminus in close structural association with the body of the catalytic unit. The catalytic entity as depicted sits directly on the membrane surface, thereby restricting its motion relative to protein substrates. membrane and to provide mobility. This appears not to be the case. As denoted by the arrow in Figure 2, there is a critical disulfide bridge linking the C-terminal region just upstream of the transmembrane segment to the body of the molecule. Therefore, the globular BACE molecule is proximal to the membrane surface and is not attached via a mobile stalk that would permit much motion. This steric localization would be expected to limit the repertoire of protein substrates that are accessible to BACE as it resides in the Golgi region. Crystal structures of BACE/inhibitor complexes have revealed much about the nature of protein-ligand interactions, and information regarding the nature of binding sites obtained by this approach will be of critical importance in the design and development of inhibitors that will be effective drugs in the treatment of AD.

γ -Secretase

γ -Secretase activity is produced in a complex of proteins and is yet to be understood in terms of the actual catalytic entity and mechanism of proteolysis. This secretase cleaves bonds in the middle of the APP segment that traverses the membrane (underlined and boldface in Figure 1), and its activity is exhibited subsequent to cleavages at the α - or β -sites. In Figure 1, the γ -secretase cleavage sites are indicated by two arrows. Cleavage at the Val⁴⁰-Ile⁴¹ bond liberates the more abundant 40-amino-acid residue A β (A β ₁₋₄₀). Cleavage at Ala⁴²-Thr⁴³ produces a minor A β species, A β ₁₋₄₂, but one that appears to be much more hydrophobic and aggregative, and it is the 42-residue A β that is believed to be of most significance in AD pathology. As was the case for APP β -site mutations, there

are human APP mutants showing alterations in the vicinity of the γ -site, and these changes, powerfully associated with the onset of AD, lead to higher ratios of $A\beta_{1-42}$.

Central to the notion of the γ -secretase is the presence of presenilins, integral membrane proteins with a mass of ~ 50 kDa. There are a host of presenilin mutations in familial AD (FAD) that are associated with early-onset disease and an increased production of the toxic $A\beta_{1-42}$. This correlation provides strong support for the involvement of presenilin in AD, and its presence in γ -secretase preparations implies that it either is a proteolytic enzyme in its own right, or can contribute to that function in the presence of other proteins. In fact, much remains to be learned about the presenilins; it has been difficult to obtain precise molecular and functional characterization because of their close association with membranes and other proteins in a complex. Modeling studies have predicted a variable number of transmembrane segments (6–8); however, presenilin function is predicated upon processing by an unknown protease to yield a 30-kDa N-terminal fragment (NTF) and a 20-kDa C-terminal fragment (CTF). These accumulate *in vivo* in a 1:1 stoichiometry within high-molecular-weight complexes with a variety of ancillary proteins. Some of the cohort proteins identified in the multimeric presenilin complexes displaying γ -secretase activity include catenins, armadillo-repeat proteins that appear not to be essential for γ -secretase function, and nicastrin. Nicastrin is a type I integral membrane protein with homologs in a variety of organisms, but its function is unknown. It shows intracellular colocalization with presenilin, and is able to bind the NTF and CTF of presenilin as well as the C83 and C99 C-terminal APP substrates of γ -secretase. Interestingly, downregulation of the nicastrin homolog in *Caenorhabditis elegans* gave a phenotype similar to that seen in worms deficient in presenilin and notch. Evidence that nicastrin is essential for γ -secretase cleavage of APP and notch adds to the belief that nicastrin is an important element in presenilin, and γ -secretase function. Efforts to delineate other protein components of γ -secretase complexes and to understand their individual roles in the

enzyme function represent a large current research effort. Recently, two additional proteins associated with the complex have been identified through genetic screening of flies and worms. The *aph-1* gene encodes a protein with seven transmembrane domains, and the *pen-2* gene codes for a small protein passing twice through the membrane. Both of these putative members of the γ -secretase complex are new proteins whose functions, either with respect to secretase activity or in other potential systems, remain to be elucidated.

At present, it is still unclear as to how γ -secretase exerts its function. What is known, however, is that γ -secretase is able to cleave at other peptide bonds in APP near the γ -site in addition to those indicated in [Figure 1](#), and is involved with processing of intramembrane peptide bonds in a variety of additional protein substrates, including notch. This lack of specificity is a major concern in developing drugs for AD targeted to γ -secretase that do not show side effects due to inhibition of processing of these additional, functionally diverse protein substrates.

Glossary

Chaperone A protein that aids in the folding and assembly of other proteins, frequently by preventing the aggregation of folding intermediates.

Cisternal maturation/progression One model of protein transport through the Golgi apparatus that suggests that secretory cargo enters a new cisternae that forms at the *cis* face of the Golgi stack, and that this cisternae and its cargo progresses or matures through the stack by the sequential introduction of Golgi modification enzymes.

Cytoskeleton A cellular scaffold formed from filament proteins in the cell cytoplasm. Microfilaments, intermediate filaments, and microtubules give shape to the cell and, together with motor proteins, participate in the movement of membrane compartments and vesicles.

Glycosylation The modification of proteins and lipids with carbohydrates in the endoplasmic reticulum and Golgi apparatus of the secretory pathway.

Proteasome Cytoplasmic protein complex that mediates the degradation of proteins. Proteins targeted for degradation are usually modified with ubiquitin.

Secretory pathway An intracellular pathway consisting of the endoplasmic reticulum, Golgi apparatus, and associated vesicles that is responsible for the folding, modification, and transport of proteins to the lysosome, plasma membrane, and extracellular space.

Translocon A protein channel in the endoplasmic reticulum membrane that allows the signal-peptide-mediated entry of newly synthesized proteins into the endoplasmic reticulum lumen and the secretory pathway.

Vesicular transport One model of protein transport through the Golgi apparatus that suggests that secretory cargo moves sequentially between stationary Golgi cisternae in transport vesicles and is modified by resident Golgi enzymes in the process.

Introduction

The eukaryotic cell is separated into several functionally distinct, membrane-enclosed compartments (Figure 1). Each compartment contains proteins required to accomplish specific functions. Consequently, each protein must be sorted to its proper location to ensure cell viability. Proteins possess specific signals, either encoded in their amino acid sequences or added as posttranslational modifications, which target them for the various compartments of the cell. The pioneering work of Dr. George Palade provided scientists with their first picture of the functional organization of the mammalian secretory pathway. Later work showed that the secretory pathway acts as a folding, modification, and quality-control system for proteins that function in the endoplasmic reticulum (ER) and Golgi apparatus, and for those that are targeted to the lysosome, plasma membrane, and extracellular space (Figure 1). This article focuses on protein targeting to and within the compartments of the secretory pathway, and how proteins within this pathway function to ensure that correctly folded and modified proteins are delivered to the cell surface and secreted from cells.

Targeting of New Proteins to the Secretory Pathway

What Kinds of Proteins Are Targeted to the Secretory Pathway?

The proteins that are targeted to the secretory pathway can be separated into two groups – those that function in the ER and Golgi to ensure proper protein folding and modification

(i.e., resident proteins) and those that are processed in the ER and Golgi and are transported to later compartments such as the lysosome, plasma membrane, and extracellular space (Figure 1). Each of these proteins not only possesses a signal to enter the secretory pathway but may also have a secondary signal to localize it to a particular organelle within the pathway.

Signals and Mechanisms of Secretory Pathway Entry

The 1999 Nobel prize in physiology or medicine was awarded to Dr. Günter Blobel for his contributions to our understanding of the mechanism of secretory pathway entry. Dr. Blobel and his colleagues found that to enter the secretory pathway, proteins are synthesized with an amino terminal peptide (called the signal peptide) that allows them to cross the membrane of the ER. The signal peptide is a stretch of 13–16 hydrophobic amino acids and is recognized by a complex of proteins and ribonucleic acid called the signal recognition particle (SRP) (Figure 2). As the signal peptide emerges from the ribosome during translation, SRP binds to it and halts translation, and then targets the new protein–ribosome complex to the cytoplasmic face of the ER membrane where it binds to the SRP receptor. Subsequently, the new protein–ribosome complex is released from SRP and its receptor, and transferred to an aqueous membrane channel known as the ‘translocon’. Translation resumes and the new protein is co-translationally transferred through the translocon into the lumen of the ER, where in many cases the signal peptide is cleaved by a specific signal peptidase (Figure 2).

Figure 1 Compartments of mammalian cells and the organization of the secretory pathway. Shown here is diagrammatic representation of the compartments of the mammalian cell. The anterograde flow of membrane and protein traffic in the secretory pathway is shown in the box. Anterograde flow is indicated by arrows. Retrograde flow between the ER and Golgi, endosome/lysosome system and Golgi, and plasma membrane and Golgi does occur, but is not shown.

Soluble and Integral Membrane Proteins

Soluble proteins are completely translocated across the ER membrane into the lumen (Figure 2). These proteins will either remain in the ER, be targeted to another organelle, or be secreted from the cell. Integral membrane proteins that possess one or more hydrophobic membrane-spanning regions will use these sequences to insert into the membrane of the ER and either stay as ER resident transmembrane proteins or be targeted to another cellular membrane. A type I membrane protein has a cleavable signal peptide and a separate hydrophobic stretch of amino acids that acts as a membrane-spanning region. This type of protein has its amino terminus in the lumen of an organelle or the outside of the cell if it reaches the plasma membrane (these are topologically equivalent), and its carboxy terminus in the cytoplasm (Figure 2). By contrast, a type II membrane protein has an uncleavable signal peptide, or signal anchor, that is usually close to the protein's amino terminus and serves a dual function as both signal peptide and a membrane-spanning region. Type II membrane proteins employ a more elaborate insertion mechanism than do type I membrane proteins. For this reason, a type II membrane protein will have its carboxy terminus in the lumen of an organelle or outside the cell if the protein reaches the plasma membrane, and its amino terminus in the cytoplasm (Figure 2).

Other proteins span the membrane several times and are called type III membrane proteins. They can start with either cleavable signal peptides or uncleavable signal anchors and possess variable numbers of hydrophobic membrane-spanning segments.

Protein Folding and Modification in the ER

The Initiation of Protein N-Linked Glycosylation in the ER

As proteins enter the ER lumen, they fold and assemble with the help of chaperone proteins. Many proteins are also co-translationally modified by the addition of carbohydrates to asparagine residues in the process of N-linked glycosylation (Figure 2). A preformed oligosaccharide, consisting of three glucoses, nine mannoses, and two N-acetylglucosamine residues ($\text{Glc}_3\text{Man}_9\text{GlcNAc}_2$), is transferred to accessible asparagine residues in the tripeptide sequence asparagine-X-serine or threonine (X cannot be proline) by the oligosaccharide protein-transferase complex. Subsequent modification by glycosidases (enzymes that remove monosaccharides) and glycosyltransferases (enzymes that add monosaccharides) in the ER and Golgi leads to the remodeling of the N-linked oligosaccharides. These N-linked carbohydrates help proteins fold, protect them from proteolytic degradation, and, in some cases, are critical for

Figure 2 Entry into the secretory pathway. Many proteins are targeted for the secretory pathway by an amino-terminal hydrophobic signal peptide that allows their co-translational translocation across the ER membrane. [1] Signal recognition particle (SRP) recognizes the new protein's signal peptide. [2] The ribosome–new protein–SRP complex interacts with the SRP receptor on the cytoplasmic face of the ER membrane. [3] The ribosome–new protein complex is transferred to the translocon channel, protein synthesis continues, and the protein moves through the aqueous channel. [4] As the new protein enters the lumen of the ER, its signal peptide is cleaved by the signal peptidase, chaperone proteins bind to aid in folding, and oligosaccharide protein transferase complex (OST) transfers oligosaccharides (arrowheads) to asparagine residues in the process of N-linked glycosylation. [5] Soluble proteins lack additional hydrophobic sequences and are translocated through the translocon to complete their folding and modification in the ER lumen. [6] Type I integral membrane proteins have a second hydrophobic sequence that partitions into the lipid bilayer and acts as a membrane-spanning segment. These proteins have their amino termini in the lumen of an organelle or outside the cell when translocated to the plasma membrane and their carboxy-termini in the cell cytoplasm. [7] Unlike proteins with cleavable amino-terminal signal peptides, type II integral membrane proteins have an uncleavable signal anchor that target the protein to the secretory pathway and then partition into the lipid bilayer to act as a membrane spanning segment. These proteins have their amino termini in the cell cytoplasm and their carboxy-termini in the lumen of an organelle or outside the cell. Soluble and integral membrane proteins that enter at the level of the ER need not stay there, and can be transported out of the ER to other locations in the pathway by membrane vesicles (see [Figure 1](#); secretory pathway box).

modulating and mediating protein and cell interactions at the cell surface and in the extracellular space.

Chaperones and the ER Quality Control System

An important function of the ER is to serve as a site of protein folding and quality control. Protein folding in the ER includes the formation of intra-molecular disulfide bonds, prolyl isomerization, and the sequestration of hydrophobic amino acids into the interior of the protein. Protein disulfide bonds are formed as the protein exits the translocon and may at first form incorrectly between cysteine residues close together in the protein's linear amino acid sequence. Thiol-oxidoreductases, such as protein disulfide isomerase (PDI), help to form and reorganize proteins' disulfide bonds into the most energetically

favorable configuration. Different types of chaperones monitor a protein's folding and prevent exit of unfolded and unassembled proteins from the ER. The chaperone BiP, originally identified as an immunoglobulin heavy chain binding protein, interacts with the exposed hydrophobic sequences of folding intermediates of many proteins and prevents their aggregation. Two chaperones called calnexin and calreticulin recognize a monoglucosylated carbohydrate structure ($\text{Glc}_1\text{Man}_9\text{GlcNAc}_2$) that is formed by a special glucosyltransferase that recognizes unfolded or misfolded proteins and adds a single glucose to the $\text{Man}_9\text{GlcNAc}_2$ structure. Proteins that are not folded properly or are not assembled into oligomers with partner subunits are prevented from exiting the ER by chaperone interactions, and can be targeted back across the ER membrane through the translocon into the cytoplasm where they are degraded by

the proteasome complex in a process called ER-associated degradation (ERAD).

Protein Transport Through and Localization in the Secretory Pathway

Vesicular Transport between the ER and Golgi

Proteins move between the ER and Golgi in vesicular carriers. These vesicles are coated with specific sets of cytoplasmic proteins that form the COP-I and COP-II coats. COP-II-coated vesicles move from the ER to the intermediate compartment/*cis*-Golgi, whereas COP-I-coated vesicles move from the Golgi back to the ER and may also mediate transport between Golgi cisternae in both the anterograde (toward the plasma membrane) and retrograde (toward the ER) directions (Figure 3). The process of vesicular transport can be separated into three stages – cargo selection and budding, targeting, and fusion. In the first stage, the COP coats serve to select cargo for exit from a compartment and help to deform the membrane for vesicle budding. They assemble on the membrane with the help of small GTPases called ADP ribosylation factor (ARF; specific for COP-I) and Sar1p (specific for COP-II). After vesicle budding, the hydrolysis of guanosine triphosphate (GTP) by ARF and Sar1p leads to the uncoating of the vesicle. This uncoating reveals other vesicle proteins that are essential for vesicle targeting and fusion. In the second and third stages, tethering

proteins on the transport vesicle and target membrane interact weakly bringing the membranes together. This allows vesicle-associated SNARE proteins (SNAP (soluble NSF attachment protein) receptor, SNARE) and target-membrane-associated SNARE proteins to form complexes. Subsequent conformational changes in the SNARE protein complex bring the membranes together for fusion. Another group of small GTPases called Rabs controls the process of vesicular transport at several levels by recruiting and activating various proteins in the pathway.

Protein Localization in the ER

Proteins involved in protein folding, modification, and quality control must remain in the ER, while proteins destined for the Golgi, lysosome, plasma membrane, or those that are secreted from the cell must exit. Exit from the ER is a selective process that involves cargo receptors that interact with COP-II coat components (Figure 3). It is likely that most resident ER proteins are not selected to exit the ER. It is clear, however, that some resident proteins escape from the ER and are retrieved from the Golgi and intermediate compartment by COP-I vesicles (Figure 3). These proteins have specific amino acid signals that allow their incorporation into COP-I-coated vesicles either by direct interaction with COP-I components or by indirectly interaction with cargo receptors. For example, BiP is a soluble ER chaperone that has the carboxy-terminal four-amino-acid

Figure 3 Comparison of two models of protein transport through the Golgi apparatus. In the vesicular transport model, cargo proteins move between the cisternae in vesicles, while Golgi enzymes are retained in their resident cisternae. [1] COP-II-coated vesicles transport new proteins from the ER to the intermediate compartment (IC). [2] Resident ER proteins that escape the ER can be retrieved from the IC in COP-I-coated vesicles. [3] COP-I-coated vesicles also transport anterograde cargo proteins between the Golgi cisternae in both a retrograde and an anterograde fashion (percolating vesicles). In the cisternal maturation model, cargo proteins enter a new cisterna at the *cis* face of the stack and are modified (matured) by resident Golgi enzymes that are continuously transported in a retrograde fashion into the sequentially maturing cisternae. [1a] COP-II-coated vesicles transport new proteins from the ER to the IC where a new *cis* cisterna forms. [2a] Resident ER proteins that escape the ER can be retrieved from the IC in COP-I-coated vesicles. [3a] Golgi enzymes are transported in a retrograde fashion in COP-I-coated vesicles to modify the cargo proteins in earlier cisternae. Mechanisms of protein exit from the TGN are common to both models: [4] clathrin-coated vesicles mediate late endosome (LE)–lysosome transport, while [5] other proteins are secreted in either a regulated or constitutive fashion to the plasma membrane or extracellular space.

sequence lysine–aspartate–glutamate–leucine (KDEL). This KDEL sequence is recognized by the KDEL receptor that mediates incorporation into COP-I vesicles moving from the intermediate compartment back to the ER. The lysine–lysine–X–X sequence (KKXX) is present at the carboxy terminus of some ER integral membrane proteins and it also mediates the retrieval of these proteins via COP-I vesicles.

ER Localization Signals and Protein Quality Control

In addition to carboxy terminal KDEL and KKXX sequences, an arginine–X–arginine signal called the RXR motif mediates the ER retrieval of integral membrane proteins. The RXR motif is often present in the cytoplasmic regions of multimeric proteins that are expressed on the plasma membrane. The RXR motif is thought to be masked during biogenesis and trafficking by various mechanisms such as folding, subunit assembly, protein–protein interactions, and posttranslational modifications that are all required for proteins to function properly at the plasma membrane. Defects in any of these processes can result in the exposure of the RXR motif, which leads to the recognition by COP-I and subsequent retrograde transport to the ER. Thus, the RXR motif serves as a check-point at the ER that ensures the export of proteins with appropriate structures and functions.

Protein Modification in the Golgi

The Golgi apparatus consists of stacks of flattened cisternae that contain enzymes and other proteins involved in the further modification and processing of newly made proteins. It is separated into *cis*- *medial*- and *trans*-cisternae, followed by a meshwork of tubules and vesicles called the *trans*-Golgi network (TGN). The process of N-linked glycosylation is completed through the action of glycosidases and glycosyltransferases localized in specific cisternae. Likewise, the glycosylation of serine and threonine residues (O-linked glycosylation) is accomplished by other glycosyltransferases. Additional modifications also occur in the Golgi. For example, proteins and carbohydrates are sulfated by sulfotransferases and some proteins are phosphorylated on serine and threonine residues by Golgi kinases. In addition, proteins such as digestive enzymes (trypsin, carboxypeptidase) and hormones (insulin) are made as inactive precursors that must be proteolytically processed to their active forms in the late Golgi or post-Golgi compartments.

Transport of Proteins through the Golgi

Currently, there are two different models to explain protein transport through the Golgi (Figure 3). The vesicular transport model proposes that proteins move sequentially between the Golgi cisterna in COP-I-coated vesicles, while the cisternae themselves are stationary. Proteins not retained in the *cis*-Golgi, for example, would be incorporated into coated vesicles and be transported to the *medial*-Golgi, and then to the *trans*-Golgi. Proteins destined for post-Golgi compartments move through successive Golgi cisternae in this fashion, being modified by the resident enzymes in each compartment (Figure 3). In the cisternal maturation or progression model, a new cisterna is formed on *cis* face of the Golgi stack from ER-derived

membrane. This requires both the anterograde transport of newly synthesized proteins from the ER in COP-II-coated vesicles and the retrograde transport of *cis*-Golgi enzymes from the pre-existing *cis* cisterna in COP-I coated vesicles. The new *cis*-cisterna and its contents progressively mature through the stack as resident Golgi enzymes are successively introduced by COP-I-coated vesicles (Figure 3). In the vesicular transport model, the resident Golgi enzymes are retained in the cisternae while the cargo moves in vesicles between the different cisternae. By contrast, in the cisternal maturation/progression model, the resident enzymes are continuously moving in a retrograde fashion, while the anterograde cargo remains in the cisternae. In a budding yeast *Saccharomyces cerevisiae*, recent imaging studies have provided strong evidence for the maturation of cisternae and the cisternal maturation/progression model. Nevertheless, evidence for both mechanisms is compelling, suggesting that they may work in parallel.

Localization of Resident Golgi Enzymes

In the context of the vesicular transport model, Golgi enzymes are retained in specific cisternae. Two mechanisms have been suggested for Golgi protein retention. The bilayer thickness mechanism suggests that the relatively short transmembrane regions of Golgi proteins prevent their incorporation into the wider, cholesterol-rich lipid bilayers of the transport vesicles destined for post-Golgi compartments (such as the plasma membrane), and, as a result, these proteins are retained in the relatively cholesterol-poor Golgi membranes. The oligomerization mechanism predicts that once an enzyme has reached its resident cisterna, it forms homo- or hetero-oligomers that prevent its incorporation into transport vesicles moving to the next compartment. In the context of the cisternal maturation/progression model, resident Golgi enzymes are actively incorporated into COP-I vesicles for retrograde transport to a new cisterna, and one might predict that the cytoplasmic tails of these proteins would interact with COP-I components to allow vesicle incorporation. Interestingly, while the membrane-spanning regions of Golgi resident proteins have been shown to be critical for their localization, evidence continues to accumulate that demonstrates a role for the cytoplasmic sequences of several Golgi proteins in their localization. It is likely that some or all of these mechanisms work together to maintain the steady-state localization of resident Golgi proteins.

Protein Exit from the Golgi and Targeting to Post-Golgi Locations

Protein Exit from the Golgi

Once proteins reach the TGN, they are sorted to post-Golgi compartments that include the lysosome, the plasma membrane, and the extracellular space (Figure 3). Trafficking to the lysosome–endosome system involves clathrin-coated vesicles similar to those that function in the uptake of proteins in endocytosis. By contrast, transport to the plasma membrane, or exocytosis, can occur either constitutively in secretory vesicles/tubules or in a regulated fashion from secretory granules found in specific cell types.

Protein Targeting to the Lysosome

The lysosome is a degradative compartment that contains numerous acid hydrolases that function to digest proteins, lipids, and carbohydrates. The trafficking of the majority of lysosomal enzymes to the lysosome requires mannose 6-phosphate residues on these enzymes' N-linked sugars. The mannose 6-phosphate residues are recognized by receptors in the TGN that mediate the incorporation of the new lysosomal enzymes into clathrin-coated vesicles destined for the late endosome compartment (Figure 3). These clathrin-coated vesicles move from the TGN and fuse with the late endosome, where a decrease in luminal pH causes the lysosomal enzymes to dissociate from the receptors. The enzymes are then transported to the lysosome, while the receptors recycle to the TGN. Some lysosomal membrane proteins that lack the mannose 6-phosphate signal are also trafficked in clathrin-coated vesicles to the lysosome, while others are transported to the cell surface, incorporated into a different set of clathrin-coated vesicles used in the process of endocytosis, and then trafficked to the lysosome via the late endosome.

Constitutive and Regulated Secretion

In many cell types, membrane-associated and soluble proteins move to the plasma membrane constitutively without a requirement for specific signals. Constitutively secreted proteins include receptors, channel proteins, cell adhesion molecules, and soluble extracellular matrix and serum proteins. Other proteins such as hormones and neurotransmitters are targeted to secretory vesicles that are involved in regulated secretion from endocrine and exocrine cells, some types of immune cells, and

neurons. These vesicles remain in a secretion-ready state until extracellular signals that lead to an increase in intracellular calcium levels trigger the exocytosis of their contents.

Microtubule and Motor Proteins in the Secretory Pathway

Vesicular trafficking between membrane compartments requires cytoskeletal filaments and motor proteins. Microtubules emerge from a structure called the microtubule-organizing center (MTOC) where the minus-ends of microtubules are anchored. Motor proteins are a class of molecular motors that are able to transport membrane vesicles by moving along the surface of the cytoskeleton. They are powered by the hydrolysis of ATP and convert chemical energy into mechanical work. For example, several types of kinesin motors transport vesicular cargo toward the microtubule plus-end, whereas cytoplasmic dynein–dynactin transports vesicles toward the minus-end. In addition, certain classes of unconventional myosins convey cargo along actin filaments (Figure 4). For example, the vesicular transport from ER to Golgi along microtubules is dependent on the dynein–dynactin complex, while trafficking in the retrograde pathway from Golgi to ER, as in the recycling of ER-resident proteins, is likely to be kinesin dependent. Kinesins also participate in the trafficking pathways that diverge from the TGN, including transport to late endosomes and sorting to constitutive and regulated secretory vesicles. Recruitment of motor proteins to membrane vesicles is facilitated by various molecules including coat proteins, modular scaffold proteins, transmembrane proteins, small GTPases, and other motor proteins.

Figure 4 Cytoskeletal filaments connecting the membrane compartments in the secretory pathway. Motor proteins utilizing the cytoskeleton for movement fall into two categories based on their substrates. Some motors such as myosin move along microfilaments through interaction with actin. Other motors such as dynein and kinesin move along microtubules through interaction with tubulin. There are two basic types of microtubule motors: plus-end motors and minus-end motors that walk in different directions along the microtubule cables within the cell. Kinesins typically walk toward the plus end of the microtubule, while the dynein–dynactin complex transports cargo by walking toward the minus end.

Glossary

Elongation factor Helper protein assisting the ribosome in the polypeptide elongation process.

Nonstandard amino acid Amino acid whose insertion is achieved by an expansion of the classical genetic code.

SECIS Selenocysteine insertion sequence of the mRNA which redefines a UGA stop codon, in a sense, codon for the insertion of selenocysteine.

Selenoprotein Protein with one or more selenocysteine residues.

Stop codon A codon signaling chain termination in protein synthesis in the classical genetic code UGA, UAA, or UAG.

tRNA RNA molecule carrying an amino acid at its 3'-end and functioning as an adaptor to incorporate the amino acid into the growing polypeptide chain according to the triplet sequence of the mRNA.

Selenoproteins contain one or more residues of the nonstandard amino acid selenocysteine, which is an analog of cysteine in which a selenol group replaces a thiol. The majority of these proteins catalyzes some oxidation/reduction function in which the selenol of the selenocysteine that is present in the active site of the respective enzyme takes part in the reaction. The advantage of having a selenol instead of a thiol lies in the fact that it confers to these enzymes a higher kinetic efficiency. In some biological systems, selenoproteins may also fulfill a structural role because of their capacity to oligomerize proteins via the formation of diselenide or mixed disulfide–selenide bridges. The biosynthesis of selenoproteins is unique since the incorporation of selenocysteine occurs co-translationally by the ribosome and not posttranslationally. Selenocysteine insertion is DNA encoded, requires the function of a cognate transfer RNA (tRNA) and of a specific translation elongation factor different from elongation factor Tu. Selenocysteine, therefore, has been designated as the 21st amino acid.

Bacterial Selenoprotein Synthesis

The structure and the function of the components involved in selenocysteine biosynthesis have been characterized to a considerable extent in the case of the bacterial system. The process can be divided into three functional steps: (1) the biosynthesis of selenocysteine in the tRNA-bound state; (2) the formation of a complex between elongation factor SelB, guanosine triphosphate (GTP), selenocysteyl-tRNA^{Sec} and the messenger RNA (mRNA); and (3) the decoding event at the ribosome. As far as it is known, though there are some major differences, similarities also exist between bacterial selenoprotein synthesis and the process characteristic of eukarya and archaea.

Selenocysteine Biosynthesis

Figure 1 summarizes the process of selenocysteine biosynthesis as it has been worked out for *Escherichia coli*. It requires the activities of three enzymes, namely, seryl-tRNA synthetase (SerS), selenophosphate synthetase (SelD), and selenocysteine synthase (SelA) plus the specific tRNA (tRNA^{Sec}). Seryl-tRNA synthetase

charges tRNA^{Sec} with L-serine, selenocysteine synthase converts the seryl-tRNA^{Sec} into selenocysteyl-tRNA^{Sec} using selenophosphate as a source for activated selenium. Selenophosphate is provided by selenophosphate synthetase from selenide in an adenosine triphosphate (ATP)-dependent reaction. The genes for these components had been identified with the aid of *E. coli* mutants isolated by Mandrand–Berthelot as being pleiotropically deficient in formate dehydrogenase activities.

tRNA^{Sec}

tRNA^{Sec} (**Figure 2**) is the key molecule of selenoprotein synthesis since it serves both as the adaptor for selenocysteine biosynthesis and for incorporation of the amino acid at the ribosome. It deviates in size, secondary structure, and in normally conserved sequence positions from canonical elongator tRNA species. Due to the elongated extra arm and the one base-pair-extended aminoacyl acceptor arm, tRNA^{Sec} species are the largest members of the elongator tRNA family. All tRNA^{Sec} species identified thus far possess a UCA anticodon, which enables them to pair with UGA stop codons (but only if these are in a special mRNA sequence context). Moreover, tRNA^{Sec} species deviate from canonical elongator tRNA species in sequence positions which are usually invariant and which are involved in the establishment of novel tertiary interactions within the molecule.

On the basis of its serine identity elements, tRNA^{Sec} is charged by the cellular seryl-tRNA synthetase, which also aminoacylates serine-inserting isoacceptors. However, both the affinity and the rate of aminoacylation are diminished in comparison to the charging of tRNA^{Ser}, resulting in an overall 100-fold reduced efficiency.

Selenocysteine synthase

The overall reaction catalyzed by selenocysteine synthase consists in the exchange of the hydroxyl group of the serine moiety of seryl-tRNA^{Sec} by a selenol group (**Figure 1**). The reaction occurs in two steps: first, the amino group of serine forms a Schiff base with the carbonyl of the pyridoxal 5'-phosphate cofactor of selenocysteine synthase leading to the 2,3-elimination of a water molecule and the formation of dehydroalanyl-tRNA^{Sec} and second, nucleophilic addition of reduced selenium to the double

Figure 1 Path of selenocysteine biosynthesis. For explanation, see text.

Figure 2 Cloverleaf presentation of the structure of tRNA^{Sec} from *E. coli*. Modified bases are shaded. Tertiary interactions via base pairing are indicated by connecting red lines, and those involving intercalation are denoted by arrows. Bases and base pairings deviating from the consensus are indicated in green.

bond of dehydroalanyl-tRNA^{Sec} from selenophosphate as a donor yields selenocysteyl-tRNA^{Sec}.

Selenocysteine synthase from *E. coli* is a homodecameric enzyme and low-resolution electron microscopy revealed that it is made up of two pentameric rings stacked on top of each other. Each of the two subunits is able to bind one molecule of seryl-tRNA^{Sec}, so the fully loaded enzyme can complex five charged tRNA molecules. As serine isoacceptor tRNAs are not recognized, the tRNA must have determinants for the specific recognition of seryl-tRNA^{Sec} by selenocysteine synthase and antideterminants for the rejection of seryl-tRNA^{Ser} species. The specificity for discrimination of the selenium donor is not as strict since the purified enzyme accepts thiophosphate instead of selenophosphate as a substrate. This results in the formation of cysteyl-tRNA^{Sec}. Therefore, the discrimination between sulfur and selenium must take place at some other step of selenocysteine biosynthesis.

Selenophosphate synthetase

Purified selenocysteine synthase does not exhibit an absolute requirement for selenophosphate as a substrate to convert seryl-tRNA^{Sec} into selenocysteyl-tRNA^{Sec}, since the reaction also occurs in the presence of high concentrations of selenide. Even sulfide is accepted although at a very low efficiency. Therefore, selenophosphate as a substrate may be necessary in one or more of the following three aspects, that is, (1) to discriminate sulfide from selenide, (2) to efficiently use low concentrations of selenium compounds, and (3) to accelerate the reaction rate effected by the activation of the trace element. Indeed, selenophosphate synthetase efficiently discriminates between sulfide and selenide, and thus excludes sulfur from intrusion into the

selenium pathway. Selenophosphate synthetase from *E. coli* is a monomeric enzyme with a unique reaction mechanism since it formally transfers the γ -phosphate of ATP to selenide with the intermediate formation of enzyme-bound adenosine diphosphate (ADP), which is subsequently hydrolyzed into adenosine monophosphate (AMP) and inorganic phosphate.

Formation of the SelB-GTP-selenocysteyl-tRNA-SECIS complex

Elongation factor Tu, which forms a complex with all 20 standard aminoacyl-tRNAs and donates them to the ribosomal A-site, displays only minimal binding affinity for selenocysteyl-tRNA^{Sec}. Consequently, insertion of selenocysteine requires the function of an alternate elongation factor, which is SelB. SelB from *E. coli* is a 70-kDa protein, which contains the sequence elements of elongation factor Tu in the N-terminal two-thirds of the molecule (designated domains I, II, and III) plus a domain IV of about 25 kDa, which can be subdivided into domains IVa and IVb. Domains I, II, and III share their functions with those of elongation factor Tu, namely the binding of guanosine nucleotides and of charged tRNA. An important difference, however, is that they can discriminate between the serylated and the selenocysteylated forms of tRNA^{Sec}. In this way, the insertion of serine instead of selenocysteine, which would lead to an inactive enzyme, is prevented. The structural basis for this discrimination ability has not yet been resolved. A second difference is that the overall affinity for GTP is about 10-fold higher than that for guanosine diphosphate (GDP), which obviates the need for the function of a guanosine nucleotide release factor, since GDP is chemically replaced by GTP. In accordance, the structure of SelB lacks those subdomains, which in elongation factor Tu are responsible for interaction with the GDP release factor EF-Ts. The 25 kDa C-terminal extension of SelB (domain IV) is required for the function in selenoprotein synthesis since its truncation inactivates the molecule. The reason is that subdomain IVb binds to a secondary structure of the mRNA (the SECIS element) coding for selenoprotein synthesis. SelB, thus, is able to form a quaternary complex with GTP and two RNA ligands, namely selenocysteyl-tRNA and the SECIS element (Figure 3). The isolated domains IV or IVb retain the binding capacity for the SECIS element. The formation of the quaternary complex follows random-order kinetics. Another important feature is that

the stability of the complex is increased when both RNA ligands are bound.

The SECIS element is a hairpin structure formed within a section of 39 bases of the selenoprotein mRNA which follows the codon specifying selenocysteine insertion at the 3'-side. The binding of SelB takes place at its apical stem-loop mini-helix of 17 nucleotides. Genetic and structural analysis showed that bases in the loop region plus a bulged-out U in the helix are required for the interaction with SelB. This apical part of the SECIS element is separated by a short unpaired region from a helix at the base of the hairpin. Pairing within this second helix is not essential but it increases the efficiency of selenocysteine insertion. An absolute requirement, however, is that the codon determining selenocysteine insertion lies within a critical distance relative to the binding site of SelB.

Bacterial SECIS elements lie within the reading frame of their selenoprotein mRNAs; they are thus subject to stringent sequence constraints in order to deliver a functional gene product. However, they do not need to be translated since they also function when placed in the 3'-untranslated region at the correct distance to the selenocysteine codon within an upstream reading frame. The sequence constraint (which depends on the protein to be formed) and the requirement for binding of SelB restricts the number of selenoprotein mRNAs to be expressed in a single organism and explains why the vast majority of selenoprotein genes cannot be heterologously expressed unless the cognate SelB gene is coexpressed. Thus, SelB and their SECIS elements are subject to coevolution.

Decoding Event at the Ribosome

In all biological systems analyzed thus far, selenocysteine insertion is directed by the opal stop codon UGA, but only if it is followed by an SECIS element at the correct distance. This violates the dogma that no codon can have more than one meaning within a single cell. The questions to be answered therefore are: (1) what prevents the UGA to be used as a termination signal; and (2) which mechanism interferes with insertion of selenocysteine at ordinary UGA stop codons?

Counteraction of stop at the UGA?

A convincing answer to the question why the selenocysteine-specific UGA codon does not function as an efficient termination signal must await structural information on the decoding complex. It is, however, clear that termination always competes with selenocysteine insertion, especially under conditions when the capacity for decoding the UGA with selenocysteine is a limiting factor. This can be, for example, a surplus of selenoprotein mRNA in relation to the amount of SelB quaternary complex, which forces the ribosome to stall at the UGA. One fact identified to be involved in the suppression of termination is that the base following the UGA at the 3'-side in selenoprotein mRNAs is predominately an A or C, which renders the UGA a weak termination signal. Moreover, the two amino acids preceding selenocysteine in the nascent polypeptide chain are predominantly hydrophobic, which counteracts the dissociation of the nascent polypeptide from the ribosome when translation pauses at a hungry codon present in the A site. However, additional mechanisms must exist, which contribute to the suppression of termination.

Figure 3 Translation of prokaryotic selenoprotein mRNA. Note that the SECIS element is within the mRNA reading frame and is complexed to domain IVb of SelB carrying selenocysteyl-tRNA^{Sec} and GTP.

Selenocysteine specificity of UGA codons

From the collinearity between the mRNA nucleotide sequence and the amino acid sequence of the translation product, it is clear that UGA determines the position where selenocysteine is to be inserted during translation. The specificity of the UGA, however, is determined by the codon context, that is, by the existence of a SECIS element at the 3'-side. The results of extensive biochemical and biophysical analysis suggest the following scenario for the decoding process: (1) SelB forms the quaternary complex at the mRNA in which the two RNA ligands display cooperativity in their interaction with the protein; (2) in this quaternary complex, SelB attains a conformation compatible for interaction with the ribosome, which then results in stimulation of GTP hydrolysis by SelB, which in turn causes the release of the charged tRNA in the vicinity of the ribosomal A-site; and (3) loss of the tRNA ligand causes the SelB protein to return to a conformation with affinity about 10-fold lower for the SECIS element. As a consequence, the mRNA is released from the protein and freed for the translation of codons downstream of the UGA. The consequence of the complex cascade of reactions is that the efficiency of the decoding of UGA with selenocysteine is lower than that of any of the standard sense codons. It is also reflected by a considerable pause occurring when the ribosome encounters the quaternary complex at the mRNA. In the absence of selenocysteyl-tRNA, binding of SelB alone to the mRNA does not retard the rate of translation.

Archaeal and Eukaryal Selenoprotein Synthesis

tRNA^{Sec} species from archaea and eukarya share several structural similarities with the bacterial counterparts, but they are more related to each other than either one is to bacterial tRNA^{Sec}. There is also considerable sequence similarity among selenophosphate synthetases from all three lines of descent rendering their annotation in genome projects easy. On the other hand, homologs for the bacterial selenocysteine synthase have not been identified yet in any of the genomic sequences from organisms known to synthesize selenoproteins.

Whereas UGA directs selenocysteine insertion in both archaea and eukarya, a fundamental difference is that the SECIS element is not positioned within the reading frame but in the 3'-nontranslated region of the mRNA. SECIS elements from organisms of the three lines of descent differ by sequence and by secondary structure. They may be positioned at different distances from the actual termination codon and/or the selenocysteine-inserting UGA codon, but a critical distance must not be underpassed. It is thought that the selective value for having the SECIS element in the nontranslated region consists in liberating it from the sequence constraint and, thus, allowing the translation of mRNAs with more than one UGA codon specifying selenocysteine insertion. Indeed, proteins

Figure 4 Translation of eukaryal selenoprotein mRNA. Note that the SECIS element is in the 3'-nontranslated region and serves as the binding site for SBP2, which in turn interacts with eukaryal SelB protein.

with up to 17 selenocysteine residues are formed in some eukaryotes and, in one instance, a polypeptide with two such amino acids is synthesized in an archaeon.

Parallel to this deviation in sequence, structure, and position of the SECIS element, there is an alteration of the structure of the archaeal and eukaryal SelB-like translation factors. Domains I, II, and III closely resemble the three homologous domains from the bacterial SelB. However, the C-terminal extension is short, less than 10 kDa, and accordingly, as expected, the archaeal and eukaryal SelB homologs do not bind to their cognate SECIS structures. In eukarya, a second protein fulfills this task, namely SBP2 (SECIS-binding protein 2) (Figure 4). There is evidence that SBP2 interacts with the SelB protein by direct contact in the decoding process. This interaction is stabilized in the presence of selenocysteyl-tRNA^{Sec}. However, the precise function of SBP2 has not yet been resolved.

Glossary

Cell cortex A specialized layer of cytoplasm beneath the plasma membrane. In animal cells, it contains actin and actin-binding proteins.

Cell cycle The sequence of events by which a cell duplicates its contents and divides into two. There is a network of regulatory proteins that governs the progression through the key events such as DNA replication, formation of the mitotic spindle, and segregation of the chromosome. The cell cycle ends with cytokinesis.

Exocyst complex Complex of conserved proteins, which is an essential part of the exocytotic apparatus.

FH proteins Formin homology proteins are conserved proteins required to assemble some types of actin structures such as actin cables (in yeast), stress fibers, and the contractile ring.

Guanosine di-/tri-phosphate (GDP/GTP) Plays an important role in tubulin stability and microtubule assembly and in signal transduction pathways via small GTPases.

Inositol phospholipids Membrane lipids containing inositol and phosphate(s) that are important in various cell-signaling pathways.

Midbody The thin intercellular bridge of cytoplasm connecting two daughter cells in late cytokinesis.

It contains a tightly packed antiparallel array of microtubules and an electron-dense matrix at its center.

Photobleach The exposure of a fluorescent probe to light such that it is rendered nonfluorescent or 'bleached'. Examining the recovery of fluorescence after photobleaching a tagged protein gives an indication of how dynamic its localization at the bleached structure is.

Polarization fluorescence microscopy Fluorescence imaging of a fluorophore that is rigidly affixed to the protein of interest. Sample is illuminated with polarized light and emission is collected after selection of light with the same axis of polarization as the excitation.

Septation In yeast, the formation of a new cell wall or septum to separate two daughter cells. Septation is separable from cytokinesis.

Small GTPase GTP-binding and hydrolyzing switch proteins that alternate between an active/on state when GTP-bound and an inactive, GDP-bound state.

Cytokinesis

Cytokinesis is the process by which one cell physically separates into two daughter cells at the end of each division cycle. In metazoan cells, the division plane, termed the cell equator, is determined by microtubules of the anaphase spindle. Thus, cytokinesis is temporally and spatially coupled to chromosome segregation, ensuring that each daughter cell receives the correct genomic content. Signals from the anaphase spindle elicit formation of a contractile ring made of actin, myosin-II, and other associated proteins, including septins under the plasma membrane at the cell equator. The cleavage furrow ingresses by a combination of ring contraction driven by myosin-II, and targeted insertion of vesicles near the furrow to supply new plasma membrane. Finally, cytokinesis is completed in a poorly understood process called abscission that involves the disassembly of the contractile ring, compaction of the microtubule midzone, and plasma membrane sealing by targeted membrane deposition and fusion (**Figure 1**).

Septins localize to the contractile ring in all organisms that have been studied. Deletion, mutation, or inhibition of septins typically results in incomplete or abortive cytokinesis, though the severity of the defect varies among organisms. This suggests a conserved function of septins in cytokinesis that is not

required for cleavage plane specification, but is required for optimal furrow ingression and/or completion.

Biochemical and Structural Properties of the Septins

Septins Bind Guanine Nucleotides and form Complexes and Filaments

Sequence analysis shows that all septins have a central globular domain containing conserved motifs found in small guanosine triphosphatases (GTPases), and most septins have a C-terminal predicted coiled-coil region of variable length. On purification, septins are found in large complexes containing multiple septin polypeptides. The septin complex purified from *Drosophila* embryos is composed of three septin polypeptides with a stoichiometry of 2:2:2. Yeast complexes contain a fourth septin subunit, and complexes from mammalian brain are heterogeneous, and may be built from at least six different septin polypeptides. When viewed by negative-stain electron microscopy (EM), a typical septin preparation appears as filaments 7–9-nm thick and of variable lengths. The shortest filament represents the complex itself and is the nonpolar building block from which the longer filaments are formed (**Figures 2(a)** and **2(b)** show a purified yeast complex).

Figure 1 Schematic illustrating the different subprocesses of cytokinesis. DNA is shown in blue, microtubules (MTs) in green, and the contractile ring (CR) in red. The CR assembles and contracts, microtubules become bundled and compacted into the midbody. Cytokinesis is completed by disassembly of the CR and MT structures. Membrane fusion in the cell–cell bridge allows final cell separation.

(b) Filaments of variable lengths. (c) Long paired filaments (Courtesy of J Frazier). (d) and (e) Higher order structures formed by a three polypeptide recombinant mammalian septin complex. Complexes polymerize into long filaments that bundle (d) and curl up to form rings (e). Coomassie-stained polyacrylamide gel analysis of complexes on the left. Scale = 100 nm. (a) Modified from Byers B and Goetsch L (1976) A highly ordered ring of membrane-associated filaments in budding yeast. *Journal of Cell Biology* 69: 717–721. (e) Reproduced from Kinoshita M, Field CM, Coughlin ML, Straight AF, and Mitchison TJ (2002) Self- and actin-templated assembly of mammalian septins. *Developmental Cell* 3: 791–802.

Purified septin complexes contain tightly bound guanine nucleotide at a level of one molecule per septin polypeptide. The GTP ratio is $\sim 2:1$ for both *Drosophila* embryos and yeast complexes. The role of bound nucleotide in septin biochemistry is still under investigation, and appears to be different from that in Ras superfamily small GTPases, whose function employs rapid nucleotide exchange and hydrolysis. Isolated septin complexes exchange bound nucleotide very slowly, and in yeast, the majority of bound nucleotide does not turn over during one cell cycle. These data suggest that GTP is bound during septin folding or complex assembly, and thereafter is not exchanged, at least on the majority of septins. Thus, bound GTP may play a structural role, analogous to GTP bound to α -tubulin, and not a regulatory role, analogous to nucleotide in β -tubulin or small GTPases.

The guanine nucleotide-binding portion of human SEPT2 was recently expressed in *Escherichia coli* and crystallized as a dimer containing GDP. In addition, the crystal structure of

a three-polypeptide human heterohexameric septin complex containing SEPT2, 6, and 7 has been determined. These X-ray data, combined with EM data on the two polypeptide *Caenorhabditis elegans* heterotetrameric septin complex and a four polypeptide heterooctomeric complex of budding yeast septins, indicate that the unit septin complex in these two systems is nonpolar. This indicates septin filaments polymerized from these complexes are not polar, in contrast to actin and tubulin. However, the orientation of the coiled-coils does provide a lateral polarity to the complex. This could be important in septin filament lateral interactions (see below) or in interactions with membrane.

Septin Filaments can form Higher-Order Assemblies

Septin heterooligomers can assemble into several different higher-order structures *in vitro*. Septin complexes from all organisms studied tend to polymerize end to end to form long filaments the same thickness as the unit complexes.

Filaments assembled from yeast septins tend to associate side by side in pairs a fixed distance apart, suggesting they are cross-bridged by one of the septin polypeptides (Figure 2(c)). Elaborate two-dimensional gauzes composed of septins closely apposed to the plasma membrane have been observed by EM of extracted budding yeast. Such assemblies illustrate how septins could, by creating a neighborhood of even loosely confined alignment or low-affinity-binding sites, collectively have a profound effect on organizing and scaffolding structural and regulator proteins.

Purified mammalian septin filaments tend to assemble into bundles, which under some conditions curl up into rings and coils of $\sim 0.7\ \mu\text{m}$ diameter (Figures 2(d) and 2(e)). This tendency to curve is apparently intrinsic to the septin complex, and may play a role in deforming the plasma membrane in cells. The rings are comparable in size and shape to several septin assemblies in cells, including the yeast bud neck (Figures 3(a)–3(d)) and septin rings formed in mammalian cells under stress (Figure 4(a)). Septin filaments reconstituted *in vitro* can also associate with F-actin bundles via the conserved scaffold protein anillin. This suggests that there is also a close association and possible coalignment of septins, anillin, and F-actin in the contractile ring during cytokinesis. Septins associate with the bundled F-actin in interphase stress fibers of mammalian-cultured cells (Figure 4(b)), but this is via an adaptor other than anillin.

Septins Interact with Inositol Phospholipids

A number of studies have suggested that septins bind directly to lipid bilayers containing inositol lipids, an activity that may be important in septin targeting or in regulating exocytosis. This capacity also suggests that the septins contribute to coupling the plasma membrane to the cortical contractile cytoskeleton during cytokinesis. The questions of how septins target to plasma membranes, and how this affects their functions, are important topics for future study.

Septin Behavior and Function in Cytokinesis

Budding Yeast

Septin proteins were originally identified in budding yeast (*Saccharomyces cerevisiae*) as the protein products of four genes CDC3, CDC10, CDC11, and CDC12. Temperature-sensitive mutations of these genes exhibited hyperpolarized growth and defects in cell wall deposition and cytokinesis. These septin polypeptides localize to the bud neck late in the G1 phase of the *S. cerevisiae* cell cycle, before the localization of other cleavage furrow components. Septin localization and assembly are controlled, at least in part, by the GTPase Cdc42, the master regulator of yeast cell polarity, and are independent of other cytoskeletal components including actin filaments. By EM, septins appear as 10-nm diameter filaments, termed neck filaments that lie circumferentially around the bud neck (Figures 3(a) and 3(b)). By immunofluorescence they can appear as an hourglass-shaped assembly coating the inside of the bud neck or as two rings, one just inside the mother and one on the bud side of the neck (Figure 3(c)). Photobleaching of GFP-tagged septins reveals that septins are quite dynamic before bud emergence, but once they

Figure 3 Septin structures/localization in *S. cerevisiae* and *A. gossypii* (a) and (b) Electron micrographs showing grazing sections through an early bud (a) and the neck of a large-budded cell (b) showing the 10-nm neck filaments (arrows in (a)). assemble into neck filaments, their turnover rate is slowed considerably, and they can be considered static. In an elegant demonstration of the dynamicity of bud neck septins, polarization fluorescence microscopy revealed that septin filaments initially lie along the mother-bud axis, and switch upon onset of cytokinesis to be oriented circumferentially (Figure 3(d)).

In budding yeast, septin localization at the bud neck is required for the subsequent recruitment of all other cytokinetic machinery, including a type II myosin heavy chain (Myo1p), its associated light chain (Mlc1p), a formin homology (FH)

protein Bni1p that is probably responsible for nucleating contractile ring F-actin, a Pombe Cdc15 homology (PCH) protein (Hof1p/Cyk2p), and an IQ motif-containing GTPase-activating protein protein (Iqg1p/Cyk1p). All of these proteins have homologs in other eukaryotes that also act in cytokinesis, but it is not clear if their recruitment to the division plane depends on septins in fission yeast or metazoans. Neck filaments are also thought to anchor a chitin synthase complex (Chs3p/4p + Bni4p) responsible for cell wall deposition during cytokinesis.

Budding yeast septins are also required for localization of many other proteins to the bud neck, in addition to the structural cytokinesis machinery mentioned above. A genome-wide screen identified 98 proteins that localize to bud necks, and many of these depend on septins for their localization. Well-characterized examples include the checkpoint kinases, Hsl1p, Gin4p and Kcc4p, a component of the mitotic exit network (MEN), Dbf2/Mob1, and several proteins involved in bud site selection including Bud4.

Septins also act to restrict diffusion of membrane proteins in the plane of the plasma membrane. The neck filaments form a fence that restricts membrane proteins to the bud, and presumably plays an important role in polarizing the yeast cell. If planar septin assemblies indeed bind to lipids of the plasma membrane, this function may be direct, as opposed to being mediated by other proteins that depend on septins for their localization. Such a diffusion barrier function may help explain the roles of septins in dendritic spine morphology and function in mammals, and in *Drosophila* ring canals, contexts in which plasma membrane compartmentalization is essential.

Overall, septins play a central role in the cell biology of budding yeast. This role reflects the importance of the bud neck in cell polarity and cell division, and the function of septins as a scaffold for localizing other proteins to this site, and restricting diffusion through it. In organisms that do not grow by polarized budding, septins may be important, but perhaps their role is not as central to the overall biology of the cell.

Ashbya gossypii

Ashbya is filamentous fungus that grows as a syncytium: because nuclear division is not coordinated with cell division, tens of nuclei exist together throughout the hyphal structure. Throughout the life cycle of *Ashbya*, the fungus elongates, forms spores, and can septate. Distinct septin structures are found, within the same cytoplasm, at the cell cortex in all these contexts, as well as at 'interregions' along the hyphal length (Figure 3(e)). Importantly, septins are not essential genes in *Ashbya*, so mutations and deletions can be made, propagated, and studied. Another characteristic that lends *Ashbya* septin structures to cell biological analysis is that they are larger than those in other fungi. Therefore, this species is likely to be a powerful model system in which to study multiple septin structures, and the interconversion among them, *in vivo*.

Fission Yeast

In fission yeast, *Schizosaccharomyces pombe*, disruption of the septin genes results in a delay in septation (cell-cell

separation), but not severe cytokinetic defects as seen in budding yeast. Septins localize to the division plane late in cytokinesis, on either side of the already-ingressing contractile ring, and as such are not required to recruit actin, myosin, or other contractile ring components. Stability of the septin ring requires the protein Mid2p, which is related to metazoan anillin, suggesting this interaction is conserved. Interestingly, mutations in components of the exocyst, a large complex involved in exocytosis, have a similar septation defect. Thus, in *S. pombe*, the septin scaffold is involved only in the completion stage of cytokinesis, perhaps to target exocytotic vesicles required for membrane fusion or enzymes required for final digestion of the septum.

Metazoa

In animal cells, septin polypeptides are recruited to the equatorial cortex and assembled into the contractile ring at the same time as, but independent of, actin and myosin-II (**Figure 4(c)**). Septin recruitment does depend on anillin. In fact, no known contractile ring proteins in metazoans depend on septins for their localization. Therefore, unlike budding yeast septins that are crucial for assembly of the contractile ring, animal septins act exclusively in its function. Perturbation of septins by gene disruption, RNA interference or microinjection of antiseptin antibodies perturbs cytokinesis in mammalian cells and fly embryos. However, septins are dispensable in some cases. For instance, nematode eggs can complete cytokinesis without septins at early developmental stages, although, furrowing is abnormally symmetric within the division plane (**Figure 4(d)**) and cytokinesis defects manifest in some cell lineages at post-embryonic stages.

In the early *Drosophila* embryo, septins are enriched on the cellularization front, an array of rings which descends among nuclei of the syncytial blastoderm. Septin localization to this structure depends on anillin. Analysis of a panel of anillin point mutants that are predicted to disrupt septin interaction indicates that anillin and septins orchestrate membrane organization during this elaborate event, in which embryo surface area increases 25-fold. How might septins regulate membrane dynamics? Physical and functional interactions have been shown between mammalian septins and syntaxins (soluble NSF attachment protein (SNAP) receptor (SNARE) proteins involved in membrane fusion during secretion) and the exocyst complex (a complex of proteins required for exocytosis). As previously mentioned, exocyst mutants in *S. pombe* have a phenotype similar to that of septin mutants. Thus, septins may

act via these partners to regulate or target vesicle insertion during furrow ingression.

Septins and anillin are also abundant in intracellular bridges between daughter cells following conventional cytokinesis and the stable bridges that form as the result of regulated incomplete cytokinesis in *Drosophila* embryos. This localization suggests that septins and anillin function together late in cytokinesis, perhaps during the complex process of completion/abscission. How might septins function in completion? As stated above, septins may act with syntaxins or the exocyst complex to regulate vesicle insertion at the intercellular bridge during completion. Additionally, septins and anillin may comprise a structure that mechanically stabilizes the fully ingressed membrane after the contractile ring has disassembled.

The differences in requirement for septins in contractile ring ingression and in cytokinesis indicate a divergence in cytokinesis mechanism that we do not understand. Septins may be more important during cytokinesis in some cells than others because of differences in (1) the amount of new membrane required for cytokinesis and (2) the time delay between completing ingression and actually separating the daughter cells.

Serine/Threonine Phosphatases

T S Ingebritsen, Iowa State University, Ames, IA, USA

Published by Elsevier Inc.

This article is reproduced from the previous edition, volume 4, pp. 27–32, © 2004, Elsevier Inc.

Glossary

Modulator protein Generally a low-molecular-weight, heat-stable protein that alters protein phosphatase activity or substrate specificity.

Protein kinase cascade A series of protein kinases arranged in a linear fashion in a signal transduction pathway such that an upstream protein kinase phosphorylates and activates the immediate downstream kinase.

Protein phosphatase An enzyme whose physiological function is to remove phosphate groups from serine, threonine, or tyrosine residues of proteins.

Targeting subunit A protein that directs a phosphatase to a specific subcellular location or a specific substrate and may also modulate substrate specificity and regulate phosphatase activity.

Transcription factor A protein that binds to a regulatory site on a gene leading to enhanced transcription of the gene.

Phosphorylation of proteins on serine, threonine, and tyrosine residues is a major mechanism for regulating the activity of cell proteins and it plays a central role in virtually all signal transduction pathways in eukaryotes. The steady-state level of phosphorylation of a protein at a particular site depends on the balance of the activities of the protein kinase(s) and protein phosphatase(s) acting on that site. Both protein kinases and protein phosphatases are important targets of cell regulation. This article focuses on the structure, regulation, and function of the two families of protein Ser/Thr phosphatases (phospho-protein phosphatase (PPP) and protein phosphatase Mg^{2+} - or Mn^{2+} -dependent (PPM)). Members of each family are present in all three domains of life (archaea, bacteria, and eukaryotes).

Protein Ser/Thr Phosphatase Catalytic Subunit Families

PPP Family

Members of this family possess a common catalytic core (280 residues) and can be further divided into four subfamilies termed PPP1, PPP2A, PPP2B, and PPP5. Three prokaryotic phosphatases: diadenosine tetraphosphatase, $\Phi 80$ phosphatase, and λ phosphatase exhibit weaker similarity to the PPP family.

PPM Family

Members include PP2C, *Arabidopsis* ABI1 and ABI2, *Arabidopsis* KAPP, *Bacillus subtilis* SpoIIE phosphatase, and pyruvate dehydrogenase phosphatase. The core PPM catalytic domains occur in diverse contexts. For example, the catalytic domain of *Arabidopsis* ABI1 is fused to an EF-hand domain, the *Arabidopsis* kinase-associated protein phosphatase (KAPP) catalytic domain is fused to a kinase-interaction domain. The kinase interaction domain of KAPP associates with a phosphorylated receptor-like protein. The N terminus of *B. subtilis* SpoIIE phosphatase is fused to a domain with 10 membrane-spanning segments.

Biochemical Characterization of Signature Protein Ser/Thr Phosphatases

PP1, PP2A, and PP2B are signature members of the PPP1, PPP2A, and PPP2B subfamilies while PP2C is the signature member of the PPM family. These four enzymes account for the majority of protein Ser/Thr phosphatase activity in cell extracts. The activities of these enzymes can be distinguished in cell extracts based on divalent cation requirements and the effects of physiological and pharmacological inhibitors (Table 1). PP1, PP2A, and PP2C have broad and overlapping substrate specificities whereas the substrate specificity of PP2B is more restricted.

PP2B requires μM Ca^{2+} for activity whereas PP2C requires mM Mg^{2+} . Inhibitor-1 (I_1) and inhibitor-2 (I_2) are PP1 modulator proteins. Okadaic acid is a pharmacological inhibitor of PPP family members. It is a polyether carboxylic acid that is a diarrhetic shellfish poison and a powerful tumor promoter. There are a number of other pharmacological inhibitors of the PPP family (e.g., microcystin, calyculin A, and cantharidin). Okadaic acid, microcystin, and calyculin A inhibit by binding to the phosphatase active site.

Three-Dimensional Structures and Catalytic Mechanism

Three-dimensional (3D) structures have been determined for two members of the PPP family (PP1 and PP2B) and for one member of the PPM family. A surprising finding was that the PPP and PPM families have similar 3D architectures even though the primary structures of the two families are unrelated. The 3D structure of the two families is quite distinct from that of the PTP family of protein Tyr phosphatases.

3D Structures

For both the PPM and PPP families, the core structure consists of a pair of mixed β -sheets that form a β -sandwich structure.

Table 1 Biochemical characterization of signature protein phosphatases

Type	Protein phosphatase	Substrate specificity	Divalent cation requirement	I_1 and I_2 inhibition	Okadaic acid inhibition (IC_{50})
1	PP1	Broad	None	Yes	20 nM
2	PP2A	Broad	None	No	0.2 nM
2	PP2B	Narrow	Ca^{2+}	No	5 μ M
2	PP2C	Broad	Mg^{2+}	No	No effect

PP2B requires μ M Ca^{2+} for activity whereas PP2C requires mM Mg^{2+} . Inhibitor-1 (I_1) and inhibitor-2 (I_2) are PP1 modulator proteins. Okadaic acid is a pharmacological inhibitor of PPP family members. It is a polyether carboxylic acid that is a diarrhetic shell fish poison and a powerful tumor promoter. There are a number of other pharmacological inhibitors of the PPP family (e.g., microcystin, calyculin A, cantharidin). Okadaic acid, microcystin, and calyculin A inhibit by binding to the phosphatase active site.

Figure 1 Active site structure and catalytic mechanism of PP1 catalytic subunit. Barford D (1996) Molecular mechanisms of the protein serine/threonine phosphatases. *Trends in Biochemical Sciences* 21: 407–412.

The catalytic sites possess a binuclear metal ion center, which has some similarity to the binuclear metal ion center of purple acid phosphatase (Figure 1). For the PPM family, the two metal ions are Mn^{2+} . In the case of the PPP family, the two metal ions are probably Fe^{2+} and Zn^{2+} , although there is some controversy about whether the second metal ion is Zn^{2+} or Mn^{2+} and also about whether the Fe is in the 2+ or 3+ oxidation state. In both cases, metal ions are coordinated with water molecules.

Catalytic Mechanism

For both the PPP and PPM family, hydrolysis of serine or threonine phosphate esters occurs through a single-step mechanism in which a metal-bound water acts as a nucleophile to attack the phosphorus atom of the substrate phosphate group (Figure 1). The metal ion acts as a Lewis acid to enhance the nucleophilicity of metal-bound water and it also enhances the electrophilicity of the phosphorus atom by coordinating the two oxyanions of the phosphate group. An active site

His sidechain donates a proton to the leaving oxygen of Ser or Thr. This catalytic mechanism is quite different from that used by the PTP family which involves formation of a phospho-enzyme intermediate.

Subunit Structure of PPP Family Members

Members of the PPP family interact with diverse sets of regulatory subunits, which direct the catalytic subunits to specific subcellular locations, alter substrate specificity and/or confer regulatory properties.

Interaction of PP1 with Diverse Regulatory Subunits

The catalytic subunit of PP1 (PP1c) interacts with >50 regulatory subunits, which fall into two classes: targeting subunits and modulator proteins. Targeting subunits direct PP1c to a wide variety of subcellular locations, including glycogen particle, myosin/actin, spliceosomes/RNA, endoplasmic reticulum, proteasomes, nuclear membranes, plasma membranes/cytoskeleton, centrosomes, microtubules, and mitochondria. Targeting subunits also modulate substrate specificities and may regulate phosphatase activity.

Modulators are generally low-molecular-weight, heat-stable proteins that alter PP1 activity or substrate specificity. The activity of some of the modulators (e.g., inhibitor-1, DARPP-32, CPI-17, and G subunit) is regulated through reversible phosphorylation.

Strong binding of many of the regulatory proteins to PP1c is mediated through a short motif termed 'RVxF'. This motif is found in two-thirds of the targeting subunits and one-half of the modulator proteins. The consensus sequence of the motif is: (K/R) x_1 (V/I) x_2 (F/W) where x_1 and x_2 may be any residue except a large hydrophobic residue. In some motifs, x_1 is absent. The RVxF motif binds to a docking site that is remote from the active site (Figure 2(a)). The docking site consists of a hydrophobic groove which binds the two large hydrophobic residues of the RVxF motif and a cluster of negatively charged residues which interact with basic residues at the N-terminal end of the motif.

Additional interactions between the PP1c and the targeting and modulator proteins are thought to strengthen binding and mediate effects on PP1 activity. For example, residues 7–11 of DARPP-32 (KKIQF) bind to the PP1c docking site whereas Thr 34 which is phosphorylated by PKA binds to the active site of the phosphatase.

Figure 2 Subunit structure of PPP family members. (a) PP1. C and R designate catalytic and regulatory subunits, respectively. The docking site on the C subunit interacts with the RVxF motif of the regulatory subunit. (b) PP2A. The labels C, B, and A designate the catalytic, regulatory, and adaptor subunits, respectively. The three-dimensional (3D) structure of the A subunit has been determined. Tandem arrays of huntingtin-elongation factor-A subunit-TOR (HEAT) motifs are present in a variety of other proteins. The labels N and C designate the amino and carboxyl termini of the A subunit. (c) PP2B. The labels A and B designate the catalytic and regulatory subunits, respectively. The B subunit has four Ca^{2+} -binding sites. The B subunit-binding, calmodulin-binding and autoinhibitor domains are on a carboxyl-terminal extension of the A subunit. The region from the end of the B subunit-binding domain to the beginning of the autoinhibitor domain is disordered in the absence of calmodulin and thus not visible in the crystal structure. (d) PP5. C and GR designate the catalytic subunit and the glucocorticoid receptor, respectively. TPR domains are characterized by a degenerate 34 amino acid sequence. The label N designates the amino terminus of the C subunit. The 3D structure of the amino-terminal extension of C has been determined in the absence of the core catalytic domain.

Interaction of PP2A with a Diverse Set of Regulatory Subunits

PP2A diversity is also generated by the interaction of a common catalytic (C) subunit with a diverse set of regulatory (B) subunits. However in this case, the regulatory subunits interact with the C subunit indirectly through an adapter subunit (A), thus forming a heterotrimeric phosphatase complex (Figure 2(b)).

Over 15 different B subunits are expressed in a tissue- and developmental-specific manner from four families of genes, termed PR55/B, PR61/B', PR72/B', and B'. Additional gene products are generated through alternate splicing. Functions of the B subunits include regulation of PP2A activity, subcellular targeting, and alteration of substrate specificity.

The A subunit is made up of 15 huntingtin-elongation factor-A subunit-TOR (HEAT) repeats which form an extended and curved structure reminiscent of a hook or the letter C. The catalytic subunit interacts with the C-terminal HEAT repeats (11–15) whereas the B subunits interact with N-terminal repeats (1–10).

Subunit Structure of PP2B

The catalytic (A) subunit of PP2B interacts with two EF-hand-type Ca^{2+} -binding proteins, an integral B subunit, which binds in the absence of calcium, and calmodulin which requires calcium for binding. The A subunit has a regulatory C-terminal extension which has binding sites for the two Ca^{2+} -binding proteins as well as an autoinhibitor site (Figure 2(c)). Binding of Ca^{2+} to the B subunit is absolutely required for phosphatase activity. PP2B activity is further stimulated by Ca^{2+} -calmodulin.

PP5

The catalytic subunit of PP5 has an amino-terminal extension with three tetratricopeptide repeat (TPR) domains. These domains are found in a variety of proteins and act as a scaffold that mediates protein–protein interaction. The TPR domains of PP5 mediate interaction of the phosphatase with the heat shock protein, hsp90, and the glucocorticoid receptor (Figure 2(d)). TPR domains also suppress the catalytic activity of PP5 25-fold.

Examples of Functions and Regulation of Protein Ser/Thr Phosphatases

PPM Family

PPM family members are involved in stress responses in animals, plants, fungi, and prokaryotes. PP2C antagonizes stress-response pathways involving two types of protein kinase cascades: mitogen-activated protein kinase and adenosine monophosphate (AMP)-activated protein kinase. Two other PPM family members (ABI1 and ABI2) play an essential role in the abscisic acid-mediated stress response of plants to water deprivation, and in prokaryotes, SpoIIE is involved in controlling sporulation.

PPM family members also have other cell functions. For example, the pyruvate dehydrogenase phosphate phosphatase is involved in controlling the types of metabolic fuels used in body tissues through a dephosphorylation reaction that activates pyruvate dehydrogenase in mitochondria.

Figure 3 (Left) Role of PP2B in T-cell activation. Raf-1, Mek, and ERK are protein kinases in the Ras signaling pathway. NFAT and AP-1 are transcription factors. NFAT are a family of transcription factors that exist in an inactive, phosphorylated state in the cytoplasm of resting T cells. These proteins are phosphorylated on multiple serine residues in a regulatory region in the amino-terminal half of the molecule. CsA and Cph designate cyclosporin and cyclophilin, respectively. (Right) Central role of DARPP-32 in the regulation of dopaminergic neurons. Inhibition of PP1 is associated with increased activity of NMDA and AMPA glutamate receptors, of L, N, and P type Ca²⁺ ion channels and CREB and with decreased activity of GABA_A receptor, Na⁺ channels, and Na⁺/K⁺ ATPase. There are a variety of other neurotransmitter receptors (opiate, adenosine, VIP) which elevate cAMP in medium spiny neurons. Glutamate acting through AMPA receptors and GABA acting through GABA_A receptors also elevate Ca²⁺ in these neurons.

PPP Family

Regulation of PP1 involving targeting subunits

There are four modes of regulation of PP1c involving targeting subunits: inducible expression of targeting subunits, allosteric regulation through targeting subunits, phosphorylation near the RVxF docking motif, and phosphorylation at sites remote from the docking motif.

The expression of two glycogen-targeting subunits in rat liver, G_L and R5, is decreased by diabetes and starvation and is restored by insulin treatment and refeeding, respectively.

G_L-PP1c is subject to allosteric regulation by glycogen phosphorylase *a* (phosphorylated, active form) which binds to a short segment at the C terminus of G_L with nanomolar affinity. Phosphorylase *a* binding inhibits the glycogen synthase phosphatase activity of G_L-PP1c but has no effect on phosphorylase phosphatase activity of the complex. This helps to coordinate the regulation of glycogen breakdown and synthesis in response to glucagon and perhaps to insulin.

G_M (muscle-specific glycogen targeting), NIPP1 (nuclear targeting), and Neurabin I (actin targeting) are phosphorylated by protein kinase A at sites near the RVxF-docking motif leading to dissociation of PP1c. In the case of G_M-PP1c, this results in decreased activity toward glycogen-bound substrates (glycogen synthase, phosphorylase *a*, and phosphorylase kinase).

The myosin-targeting protein M110 is phosphorylated on sites (Thr 697 and Ser 435) that are distant from the docking motif. The complex of PP1c with M110 is involved in regulating muscle contraction in smooth muscle and nonmuscle cells. Phosphorylation of Ser 435 occurs during mitosis and leads to activation of PP1c and enhanced binding to myosin II.

PP2A

One of the best-documented roles of PP2A is in the regulation of animal growth and development. A role in cell growth was first suggested by the potent inhibition of PP2A by the tumor promoter okadaic acid. Additionally, the β -isoform of the A subunit of PP2A has been identified as a candidate tumor-suppressor gene and the myeloid-leukemia-associated protein SET is a potent inhibitor of PP2A.

PP2A dephosphorylates and inactivates protein kinases involved in growth-regulatory signal transduction pathways (e.g., extracellular signal-regulated protein kinase (ERK) and Mek MAP kinases, protein kinase C, and protein kinase B). Additionally, PP2A is an important cellular target of the SV40 and polyoma DNA tumor viruses. Viral proteins associate with the AC dimer and displace B subunits. This leads to stimulation of growth-related (ERK/Mek) MAP kinase pathways and cell growth.

Genetic approaches in budding and fission yeast as well as in *Drosophila* demonstrate that PP2A has an essential role in regulating the cell cycle. Additionally, PP2A interacts with components of the Wnt signaling cascade, which controls the epithelial–mesenchymal transition during vertebrate development.

Central role of PP2B in T-cell activation

Stimulation of the T-cell receptor leads to the activation of dual signal transduction pathways involving Ca^{2+} and Ras (Figure 3, left). Elevation of intracellular Ca^{2+} results in activation of PP2B, which dephosphorylates nuclear factor of activated T cells (NFAT). This leads to activation of NFAT as a transcription factor and translocation of the NFAT from the cytoplasm to the nucleus. The Ras pathway activates a nuclear transcription factor (AP-1) through a protein kinase cascade. NFAT and AP-1 bind cooperatively to DNA regulatory sites resulting in enhanced transcription of cytokine, cell surface receptor, and transcription factor genes.

PP2B is the site of action for the immune-suppressant drugs, Cyclosporin A and FK506, used to prevent rejection in organ transplant procedures. The use of these drugs has revolutionized organ transplant therapy. The two drugs interact with separate intracellular-binding proteins (cyclophilin and FK506-binding protein) and the resulting complexes bind to and inhibit the activity of PP2B. This in turn inhibits T-cell activation by suppressing transcriptional activation through the NFAT:AP-1 complex.

Similar dual pathways involving PP2B and NFAT family members have been implicated in angiotensin-II-induced cardiac hypertrophy and in the morphogenesis of heart valves.

DARPP-32

DARPP-32 (dopamine and cyclic adenosine 3',5'-monophosphate-regulated phosphoprotein, 32 kDa) is a specific inhibitor of PP1. It is expressed at high concentrations in medium spiny neurons of the neostriatum where it plays a central role in integrating responses to dopamine (acting via the cAMP) and glutamate (acting via Ca^{2+}) in dopaminergic neurons (Figure 3, right). Diseases associated with defects in dopaminergic neurotransmission include Parkinson's disease,

Huntington's disease, attention deficit hyperactivity disorder, and schizophrenia.

Activation of the cAMP pathway in dopaminergic neurons leads to increased phosphorylation of DARPP-32 on Thr 34 and inhibition of PP1. This results in increased phosphorylation of neurotransmitter receptors, voltage-gated ion channels, an electrogenic ion pump (Na^+/K^+ ATPase), and a transcription factor (CREB).

By contrast, glutamate acting through N-methyl-D-aspartate (NMDA) receptors promotes dephosphorylation of brain proteins through activation of a protein phosphatase cascade involving PP2B and PP1. Activation of NMDA receptors elevates Ca^{2+} , which activates PP2B. This leads to DARPP-32 dephosphorylation by PP2B and activation of PP1 through relief of inhibition by DARPP-32.

Glossary

Autoreceptor A receptor on the neuronal cell body or presynaptic terminal that can regulate its own cell firing and/or neurotransmitter release and synthesis.

Constitutive activity Ability of a receptor to activate second messenger pathways without the binding of an external ligand.

Functional selectivity The ability of a receptor to couple to more than one signal cascade.

Heteroreceptor A presynaptic receptor that regulates the release other than its own ligand.

RNA editing A process whereby the nucleotide sequence of RNA transcripts are chemically altered.

Serotonin Synthesis and Metabolism

5-Hydroxytryptamine (5-HT) is a neurotransmitter in both invertebrates and vertebrates. 5-HT is found in the central nervous system, enterochromaffin cells, gastrointestinal (GI) tract, and platelets. 5-HT is synthesized from the essential amino acid tryptophan by the rate-limiting enzyme tryptophan hydroxylase and a ubiquitous l-aromatic amino acid decarboxylase. 5-HT is released into the synaptic cleft by exocytosis of vesicles in a TTX-sensitive and Ca^{2+} -dependent manner. Inactivation of 5-HT is mediated by reuptake into the presynaptic terminal through a Na^{+} -dependent 5-HT transporter. 5-HT is metabolized into the inactive form, 5-hydroxyindole acetic acid, by the enzymes monoamine oxidase and aldehyde dehydrogenase. Synaptic 5-HT concentrations can fluctuate and be manipulated by environmental influences and pharmacological agents. For instance, restriction of dietary tryptophan or chemical inhibitors of tryptophan hydroxylase reduces brain levels of 5-HT, while selective 5-HT reuptake inhibitors such as escitalopram (Lexapro) and fluoxetine (Prozac) increase the amount of synaptic 5-HT. Released serotonin acts on multiple 5-HT receptors found throughout the body in various tissues including brain, spinal cord, heart, blood, and gut.

Serotonin Receptor Structure and Function

5-HT receptors are classified and characterized by their gene organization, amino acid sequences, pharmacological properties, and second-messenger coupling pathways. With the exception of the 5-HT₃ receptor, the 5-HT receptor family consists of guanine nucleotide triphosphate (GTP)-binding proteins (G-protein)-coupled receptors (GPCRs). The basic protein structure is predicted to contain seven transmembrane regions, three intracellular loops, and three extracellular loops, with the amino terminus being extracellular and carboxy terminus, intracellular (Figure 1(a)). These receptors are linked to their signal transduction pathways through G-proteins. The sequence of events involves the activation of the cell-surface receptor by 5-HT or drugs, binding of receptor and G-protein, which promotes the exchange of bound guanine nucleotide diphosphate for GTP on

the G-protein. The G-protein is comprised of α , β , and γ subunits; the $\beta\gamma$ dimer dissociates when receptor binds and both $G\alpha$ and $G\beta\gamma$ have the ability to interact with effector enzymes. The subunit interactions promote activation or inhibition of adenylate cyclase or activation of phospholipase C (PLC). In turn, the effector enzymes generate second messengers that regulate cellular processes such as Ca^{2+} release and protein kinases and phosphatases. This multistep enzymatic process amplifies receptor signal, and provides the possibility of regulation and cross-talk at multiple levels. We have grouped the numerous 5-HT receptors family by their traditional (primary) G-protein-second-messenger linkage (Table 1), and then the multiple levels of signal diversity generated by RNA splicing, RNA editing, and promiscuity of receptor G-protein activation are discussed.

Serotonin Receptors That Inhibit Adenylyl Cyclase

The five members of the 5-HT₁ receptor family (5-HT_{1A}, 5-HT_{1B}, 5-HT_{1D}, 5-HT_{1E}, and 5-HT_{1F}) and the 5-HT₅ receptor (5-HT_{5A}, 5-HT_{5B} subtype) couple primarily through $G_{\text{zi/o}}$ proteins to inhibit the membrane-bound enzyme, adenylyl cyclase (AC). This inhibition of AC leads to a decrease of cyclic 3'/5'-adenosine monophosphate (cAMP) molecules (Figure 1(b)). The 5-HT₁ receptors are the best characterized of this family. High densities of 5-HT_{1A} receptors are found on the cell bodies of 5-HT neurons in brainstem nuclei, especially the dorsal raphe. In the dorsal raphe, the 5-HT_{1A} receptor functions as an autoreceptor that reduces 5-HT cell firing when activated. The receptor elicits neuronal membrane hyperpolarization by activating G-protein-linked K^{+} channels. In addition, 5-HT_{1A} receptors are located on postsynaptic sites in the hippocampus and other limbic brain regions where they also produce hyperpolarization by opening K^{+} channels. 5-HT_{1A} receptors may have a possible role in anxiety and are targets of a class of antianxiety drugs. The 5-HT_{1A} receptor is also involved in thermoregulation, hormone secretion, and possibly enhancing the effectiveness of antidepressants. Of the other 5-HT₁ receptors, most is known about the 5-HT_{1B} and 5-HT_{1D} subtypes. These receptors are found in basal ganglia and frontal cortex and function as terminal autoreceptors or heteroreceptors that

Figure 1 (a) Schematic drawing of the basic components of a G-protein-coupled receptor illustrating the extracellular amino terminus, seven transmembrane domains, three intracellular loops, three extracellular loops, intracellular carboxy terminus, and heterotrimeric G-protein. (b) The primary signaling pathways of the G-protein-coupled receptors. Activation of $G_{\alpha i/o}$ protein inhibits AC resulting in the decrease of cAMP production. Receptors that stimulate AC through $G_{\alpha s}$ results in increased production of cAMP, with subsequent activation of protein kinase A (PKA). Stimulation of PLC β through $G_{\alpha q}$ results in the cleavage of PIP_2 into IP_3 and DAG.

Table 1 Signaling linkages of 5-HT receptors

modulate neurotransmitter release. 5-HT_{1B/1D} heteroreceptors have been proposed to regulate the release of acetylcholine, glutamate, dopamine, norepinephrine, and γ -aminobutyric acid (GABA). Pharmacological and genomic knockout studies suggest that 5-HT_{1B} receptors are involved in aggressive behavior. 5-HT_{1D} receptors have a role in migraine headaches and many antimigraine drugs target this receptor. Less is known about 5-HT_{1F}, 5-HT_{1E}, and 5-HT₅ receptors primarily due to the lack of specific ligands. 5-HT_{1F} receptors are a target for antimigraine medication and 5-HT₅ receptors appear to have a role in circadian rhythms, mood, and cognition.

Serotonin Receptors Linked to Activation of Adenylate Cyclase

5-HT₄, 5-HT₆, and 5-HT₇ receptors are all coupled to activation of AC. These receptors are linked via the G-protein, G_{α_s} , to AC producing an increase cAMP production (Figure 1(b)). Historically, the first signal transduction pathway to be linked to a 5-HT receptor was stimulation of AC, characterized in mouse collicular neurons. This receptor now known as the 5-HT₄ receptor, which is also found in hippocampus and is involved in learning and memory, has been linked to modulation of release of acetylcholine, dopamine, 5-HT, and GABA. In the peripheral tissues, the 5-HT₄ receptor can influence GI function. The receptor is expressed in both enterochromaffin cells and enteric neurons, where it releases acetylcholine in the ileum, contracts the esophagus and colon, and promotes ion transport in the gut. In addition, the 5-HT₄ receptor elicits cardiac contraction. Due to the paucity of specific ligands less is known about the 5-HT₆ and 5-HT₇ receptors. 5-HT₆ receptors are found in the striatum, amygdala, nucleus accumbens, hippocampus, and cortex. Limited pharmacological data suggest that 5-HT₆ receptors modulate neurotransmitters such as acetylcholine, glutamate, and dopamine. This exciting data support that 5-HT₆ receptors could be a target for cognitive-enhancement therapeutics for Alzheimer's disease and schizophrenia. 5-HT₇ receptors are widely expressed in the brain, with highest expression levels in the thalamus and the hippocampus. The 5-HT₇ receptor may have role in circadian rhythms and thermoregulation. Both 5-HT₆ and 5-HT₇ receptors

have high affinity for many of the atypical antipsychotics leading to speculation of a role for these receptor subtypes in schizophrenia.

Serotonin Receptors Coupled to the Activation of PLC

The 5-HT₂ class of receptor (subtypes 2A, 2B, and 2C) activates the membrane-bound enzyme PLC that catalyzes the degradation of the inositol lipid, phosphatidylinositol 4,5 bisphosphate (PIP₂) with the production of inositol 1,4,5 triphosphate (IP₃) and diacylglycerol (DAG) (Figure 1(b)). IP₃ mobilizes Ca²⁺ from intracellular storage sites; Ca²⁺ then induces multiple responses in the cell including activation of calcium/calmodulin-dependent protein kinase enzymes that phosphorylate protein substrates in the cell. DAG activates another kinase, protein kinase C. The 5-HT₂ receptors are coupled via the G-protein G_{αq} or G_{α11} to activation of PLC.

In the brain, 5-HT_{2A} receptors are found in cerebral cortex, claustrum, basal ganglia, and thalamus. It is thought that hallucinogenic drugs exert their psychotropic action by activating 5-HT_{2A} receptors. Activation of cortical 5-HT_{2A} receptors leads to membrane depolarization and opening of K⁺ channels. In the periphery, 5-HT_{2A} receptors are involved in smooth muscle contraction, platelet aggregation, proliferation of arterial fibroblasts, and arterial vasoconstriction. In addition, 5-HT_{2A} receptors are also found in the spinal cord, where they may have a role in pain. The 5-HT_{2B} receptor was first described from the stomach fundus and later was identified in the gut, heart, kidney, liver, and with moderate expression in the lung and cardiovascular tissues. The most important function of this receptor is during development, where it coordinates the proper formation of structures such as the heart and brain.

The 5-HT_{2C} receptor is found in choroid plexus, where it regulates cerebral spinal fluid production and ion exchange between the cerebral spinal fluid and brain. The 5-HT_{2C} receptor is also found in various brain regions such as cortex, amygdala, basal ganglia, hippocampus, and thalamus. 5-HT_{2C} receptors can modulate mesolimbic dopamine neurotransmission, which may be a therapeutic target for treating substance abuse. 5-HT_{2C} receptors are proposed to be involved in anxiety, obesity, and food intake. Moreover, atypical antipsychotic drugs block the activation of 5-HT_{2A} and 5-HT_{2C} receptors indicating that these receptors may be involved in the pathophysiology of schizophrenia.

The Serotonin 3 Receptor Is a Ligand-Gated Ion Channel

The 5-HT₃ receptor is different from the other 5-HT receptors in that it forms an ion channel that regulates the flux of ions. The structure of receptor is a pentamer, similar to the nicotinic acetylcholine receptor. The receptors are found on neurons in the hippocampus, nucleus tractus solitarius, and area postrema, as well as in the periphery. They are located on pre- and postganglionic autonomic neurons and alter GI tract motility and intestinal secretion. When activated by 5-HT, the receptor triggers rapid depolarization due to an inward current by opening a nonselective cation channel (Na⁺, Ca²⁺ influx, and K⁺ efflux). The receptor is possibly involved in nausea, vomiting, and irritable bowel syndrome.

Alternative Splice Variants of Serotonin Receptors

Functional diversity of proteins can be produced by alternative splicing events. Many of the 5-HT receptor genes contain introns that are subject to alternative splicing with the generation of multiple receptor messenger RNAs (mRNAs) encoding slightly different proteins, referred to as isoforms. Seven carboxy-terminal splice variants of the 5-HT₄ receptor have been described. The most interesting feature of these splice variants is the level of constitutive activity of the receptor, which is markedly increased. Constitutive activity is the ability of a receptor to activate second-messenger pathways spontaneously without the binding of an external ligand. Four carboxy-terminal splice variants of the 5-HT₇ receptor have been identified. The functional consequence of these variants is uncertain. An alternatively spliced variant of the 5-HT_{2C} receptor has been described, which encodes a truncated, nonfunctional protein. More work needs to be done to determine the physiological relevance of these RNA-splicing events; nonetheless it is clear that this process leads to additional diversity in 5-HT receptor signaling.

RNA Editing Produces Multiple Functional 5-HT_{2C} Receptor Isoforms

The 5-HT_{2C} receptor undergoes a unique process termed RNA editing to yield multiple receptor variants. RNA editing is an enzymatic reaction that alters nucleotide sequences of RNA transcripts. For the 5-HT_{2C} receptor, five encoded adenosine residues are converted to inosines by double-stranded RNA adenosine deaminases. In the human 5-HT_{2C} receptor, the adenosines within the predicted intracellular second loop can be converted to inosine at the RNA level resulting in multiple mRNA species with the potential to encode 24 different protein variants (Figure 2). The extensively edited isoforms have different abundances in brain tissue, and the translated proteins exhibit different binding properties, and differential activation of second-messenger systems. For example, 5-HT exhibits a decreased potency when activating the fully edited, valine-glycine-valine (VGV), isoform of the human receptor compared with the unedited, isoleucine-asparagine-isoleucine (INI), form and there is a rightward shift in the dose-response curve for phosphoinositide hydrolysis. In addition, editing can alter the ability of 5-HT_{2C} receptors to couple to multiple G-proteins. For example, the nonedited 5-HT_{2C} receptor functionally couples to G_{αq} and G_{α13}, whereas the edited 5-HT_{2C} receptors has loss coupling to G_{α13}. RNA editing may have clinical significance; studies reveal associations between editing profiles and depressed suicide victims, schizophrenia, anxiety, depression, and memory. However, more work needs to be done to confirm a linkage between these clinical findings and 5-HT_{2C} receptor RNA editing.

Single-Nucleotide Polymorphisms Occur in the Serotonin Receptor Family

Normal genetic variations (single-nucleotide polymorphism, SNP) have been identified in almost all 5-HT receptors.

Figure 2 The positions of the editing sites within human 5-HT_{2C} receptors RNA and amino acid sequences are shown for hINI, hVSV, and hVGV edited isoforms of the 5-HT_{2C} receptor. These editing sites are located in the putative second intracellular loop.

Polymorphisms in the coding region of the gene have the potential to alter the receptor's ability to bind ligand, to activate signal transduction pathways, or to adapt to environmental influences. For example, a polymorphism in the amino terminus of the human 5-HT_{1A} receptor attenuates the down-regulation and desensitization produced by the agonist 8-OH-DPAT. A polymorphic variant in the 5-HT_{1B} receptor in the putative third transmembrane domain alters the binding of the antimigraine drug, sumatriptan. Another example is the SNP, H452Y, in the 5-HT_{2A} receptor which appears with the frequency of 9% in the general population and produces a change in the receptor's ability to desensitize after agonist stimulation. This SNP has been associated with attention-deficit hyperactivity disorder and antipsychotic effectiveness. Currently, efforts are being made to link the occurrence of 5-HT receptor polymorphisms with various pathological disorders. Future progress in pharmacogenomics (using genetic information to predict drug response) may potentially lead to better design of serotonergic drugs to reduce side effects and target subpopulations of patients with specific therapies dependent on their genetic profile.

Functional Selectivity and Cross-Talk between 5-HT Receptor Signal Transduction Pathways

Functional selectivity is the ability of a receptor to couple to more than one signal transduction pathway. For example, the 5-HT_{1A} receptor can both inhibit and activate AC. As mentioned above, the primary coupling of this receptor is G_{α_{i/o}} with subsequent inhibition of AC; this has been demonstrated both *in vivo* and in cultured cell systems. However, this receptor has been shown to activate AC, mediated by βγ subunits released from G_{α_{i/o}}, rather than G_{α_s} protein. This activation seems to require high receptor occupancy and high expression

levels in cell-expression systems. In addition, depending on cell type and experimental conditions the 5-HT_{1A} receptor can activate or inhibit PLC. Many studies suggest that the G-protein βγ subunits play a role in such cross-talk between signaling pathways. The 5-HT_{2C} receptor (as well as the 5-HT_{2A} receptor) is another promiscuous receptor that may activate multiple signal transduction pathways. The primary coupling of 5-HT_{2C} receptors is to activate PLC activity via G_{α_q}/G_{α₁₁} proteins to produce IP₃ and DAG. However, this receptor can activate other phospholipases, for example, phospholipase D through G_{α₁₃} proteins and free βγ subunits. Phospholipase D can influence many neuronal functions including endocytosis, exocytosis, vesicle trafficking, and cytoskeletal dynamics. In addition, 5-HT_{2A} and 5-HT_{2C} receptors can activate phospholipase A-2 activity that leads to the release of arachidonic acid and potential formation of bioactive eicosanoids such as the prostaglandins. There is evidence that 5-HT_{2A} and 5-HT_{2C} receptors differentially activate PLC compared to PLA2, dependent on the specific agonists employed. Moreover, there may be differences in the desensitization of these two pathways after repeated agonist treatment. The release of arachidonic acid can result in the activation of K⁺ channels, regulation of neurotransmitter release, and can be a retrograde messenger. Another aspect of functional selectivity is receptor oligomerization, either as homodimers or as heterodimers, which can produce another level of diversity of receptor signaling. It is becoming apparent that specific 5-HT receptors interact with many G-proteins, thereby regulating multiple signal transduction pathways. This diversity may be a target for future therapeutics and interventions.

Summary: Potential Role of Receptor Diversity

There has been much speculation on the origin and significance of the 5-HT receptor diversity. One possible explanation

for the numerous subtypes and variants is that the 5-HT neurotransmitter system emerged early during evolution. Thus, there has been ample time for genetic variation and divergence to occur in the genes encoding for the receptor proteins. Whatever the process of receptor diversity, the multiple receptor signaling has considerable biological significance. For example, inputs to the dorsal raphe nucleus are integrated into global 5-HT release, via both synaptic and volume transmission, which, in turn, can modulate multiple and diverse neuronal functions based on receptor subtype. Thus, one transmitter (5-HT) with multiple receptors/ multiple pathways can introduce levels of complexity, yet specific physiological responses, that are localized to a given brain region or neural system. These responses can be cell-type specific or even cell-compartment specific. Furthermore, a level of fidelity is introduced based on the receptor's relative affinity for 5-HT and localization of 5-HT receptors, synaptic or perisynaptic. The exact nature of this diversity is at present unclear; however, the physiological implications are quite apparent, when considering the diverse role of these receptors in many physiological functions and disease states.

Glossary

Immunoglobulin superfamily (IgSf) Proteins that have modules homologous to those of antibodies (immunoglobulins). This is an evolutionarily ancient group of proteins whose appearance actually predated the emergence of the immunoglobulins themselves.

I-type lectins Proteins (other than antibodies or T-cell receptors) in which immunoglobulin-like modules mediate binding to glycans (sugar chains).

Sialic acids These acids are a diverse family of nine-carbon acidic sugars that typically occupy a terminal position on glycan chains attached to the cell surface of higher animals of the deuterostome lineage.

Siglecs A major subset of the I-type lectins. Name is based on their defining properties, as sialic acid recognizing IgSf lectins with canonical amino-terminal sequences.

Historical Background and Definition

Sialic acids (Sias) are a family of nine-carbon acidic sugars that typically occupy a terminal position on glycan chains attached to the cell surface of higher animals. The immunoglobulin superfamily (IgSf) is an evolutionarily ancient group of proteins whose appearance predated the emergence of the immunoglobulins themselves. Until the 1990s, it was assumed that IgSf members (other than some antibodies) did not mediate carbohydrate recognition. Independent work on sialoadhesin (Sn, eventually Siglec-1, a protein on certain macrophage subsets) and on CD22 (eventually Siglec-2, a protein on mature B cells) revealed that their first Ig V-set-like domains could mediate Sia recognition. Homologous features of this V-set Ig-like domain and the adjacent C2-set domain then led to the discovery that two other previously cloned molecules – CD33 (eventually Siglec-3) and myelin-associated glycoprotein (MAG, eventually Siglec-4) – also had Sia-binding properties. Following consultation among all researchers working on these proteins, the common name Siglec (suggested by A. Varki) and a numbering system were agreed upon. Criteria for inclusion of IgSf-related proteins as Siglecs are: (1) the ability to recognize sialylated glycans and (2) significant sequence similarity within the N-terminal V-set and adjoining C2-set domains. Evaluation of the human and mouse genomes eventually defined 16 primate and eight mouse molecules that fulfill these criteria. Primates have many more Siglecs than rodents and many of these are rapidly evolving.

Two Broad Subgroups of Siglecs

While Siglecs -1, -2, -4, and -15 appear to be evolutionarily rather conserved, the CD33/Siglec-3-related subgroup (Primate Siglecs -3 and -5–16) are rapidly evolving. Some CD33/Siglec-3-related Siglecs appear to have evolved as hybrids of pre-existing genes and/or by gene conversion. For these reasons, sequence comparisons alone do not allow the conclusive designation of the ortholog status of all genes, and additional features such as gene position and exon structure must be taken

into account. As such issues cannot always be resolved, some mouse Siglecs have been assigned an alphabetical designation.

Common Structural Features

All Siglecs are single-pass type 1 integral membrane proteins with extracellular domains consisting of uniquely similar N-terminal V-set Ig domains, followed by variable numbers of C2-set Ig domains, ranging from 16 in Sn/Siglec-1 to 1 in CD33/Siglec-3. Crystal structures for mouse Siglec-1 and human Siglec-7 indicate (Figure 1) that the V-set immunoglobulin-like fold has several unusual features, including an intra-beta sheet disulfide and a splitting of the standard beta strand G into two shorter strands. These features along with certain key amino acid residues appear to be requirements for Sia recognition. In particular, a conserved arginine residue is involved in a salt bridge with the carboxylate of Sia, in all instances studied to date.

Cell-Type Specific Expression

With the exception of MAG/Siglec-4, Siglec-6, and Siglec-12, expression so far appears to be confined to the hematopoietic and immune systems. Within these systems, each Siglec is expressed in a cell-type specific fashion, suggesting that each may be involved in discrete functions. However, systematic studies of Siglec expression outside the hematopoietic system and during development have not yet been done.

Genomic Organization and Phylogeny

Based on searching for the canonical functional amino acids in the V-set domain of the typical Siglec, there is so far no evidence for Siglec-like molecules in prokaryotes, fungi, or plants, or in animals of the protostome lineage, including organisms for which the complete genome is available. By contrast, it is relatively easy to find Siglec-like V-set domains in many vertebrate taxa. While the conserved Siglecs (-1, -2, -4, and -15) have relatively clear-cut single orthologs that can be identified in

Figure 1 Domain structures of the known Siglecs in humans and mice. There are two main subgroups of Siglecs: one evolutionarily conserved group contains sialoadhesin (Siglec-1), CD22 (Siglec-2), MAG (Siglec-4), and Siglec-15, and the other group contains the rapidly evolving CD33-related Siglecs. In humans, Siglec-12 has lost its arginine residue required for sialic acid binding and Siglec-13 is deleted. ITIM, immunoreceptor tyrosine-based inhibitory motif. The *plus sign* indicates the presence of a charged residue in the transmembrane domain, which has been shown to interact with the immunoreceptor tyrosine-based activatory motif (ITAM)-containing adaptor proteins DAP12 and DAP10. Reproduced with permission from the Consortium of Glycobiology Editors, originally figure 32.1 in Varki A, Cummings RD, Esko JD, et al. (eds.) (2009) *Essentials of Glycobiology*, 2nd edn. Cold Spring Harbor, NY: Cold Spring Harbor Laboratory Press.

most species, the remaining CD33/Siglec-3 related Siglecs appear to have been evolving rapidly. Most of the latter genes are clustered together in an ~500 kb region on human chromosome 19q13.3–13.4 and the syntenic regions of other animals.

Siglec Recognition of Sialic Acids and Their Linkages

The first two Siglecs discovered (Sn/Siglec-1 and CD22/Siglec-2) had strikingly different binding properties for sialosides – with Sn preferring α 2–3 linked targets and CD22 being highly specific for α 2–6 linkages. In the latter case, the binding affinity was in the low micromolar range. MAG/Siglec-4 also has an extended binding site that is even highly specific for the underlying sugar chain. There is also variable preference for certain types of sialic acids, with Sn and MAG not tolerating the common *N*-glycolyl modification of Sias. However, the CD33/Siglec-3-related Siglecs are generally more promiscuous in their preferences for different types and linkages of Sias. Of course, many of the less common linkages and types of sialic acids have not been studied for Siglec recognition. The Golgi enzymes that are potential regulators of Siglec functions are primarily the sialyltransferases and the enzymes which modify sialic acids. Some Siglecs also show preferences for certain macromolecular ligands, for example, CD45 and IgM for CD22/Siglec-2, the mucins CD43, and Muc-1 for

Sn/Siglec-1, CD24 for Siglec-10/H, and specific brain gangliosides for MAG/Siglec-4.

Potential Effects of Neu5Gc Loss on Human Siglec Biology

The most common Sias of mammalian cells are *N*-acetylneuraminic acid (Neu5Ac) and *N*-glycolylneuraminic acid (Neu5Gc). Humans are a known exception, because of a mutation in cytidine mono-phosphate (CMP)-sialic acid hydroxylase, which occurred after the time (~5–7 Mya) when we shared a common ancestor with great apes. The resulting loss of Neu5Gc and increase in Neu5Ac in humans could have potentially altered the biology of the Siglecs. For example, human cells have a higher density of Sn/Siglec-1 ligands than great apes, the distribution of Sn-positive macrophages in humans is different and a much larger fraction of human macrophages is positive. Other evidence indicates that there are multiple human-specific changes in Siglec biology that may be at least partly related to the loss of Neu5Gc. These include binding changes (in Siglecs -5, -7, -9, -11, -12, and -14); expression pattern changes (in Siglecs -1, -5, -6, and -11); gene conversion (*SIGLEC11*); and deletion or pseudogenization (*SIGLEC13*, *SIGLEC14*, and *SIGLEC16*). Overall, Siglec changes in humans seem to be much more prominent than

in the closely related great apes, suggesting that sialic acid biology was a hot spot in human evolution.

Masking and Unmasking of Siglec-Binding Sites on Cell Surfaces

The initial assumption was that Siglecs were involved in inter-cellular adhesion. However, in most instances, their binding sites appear to be masked by Sias on the same cell surfaces on which they are expressed. Of course, external ligands with high affinity/avidity can still compete for the endogenous masking ligands. There is also some evidence that unmasking can occur under certain conditions, but it is not known if this is biologically relevant. Overall, the significance of Siglec masking is relatively unclear at this time.

Signaling Motifs in Cytosolic Tails

The inhibitory CD33-related Siglecs (Siglecs -3 and -5-12) have conserved tyrosine residues in the cytosolic tails, one of which corresponds to a canonical immunoreceptor tyrosine-based inhibition motif (ITIM). Various *in vitro* manipulations of these receptors indicate that these tyrosines are indeed targets for phosphorylation and that they can modulate signaling events by recruiting certain tyrosine phosphatases such as SHP-1 and SHP-2. However, the true *in vivo* biological functions of these signaling motifs remain somewhat obscure. Another major unresolved question is: what is the connection between extracellular sialic acid recognition and signaling via the cytosolic motifs? Even less is known about the functions of the more recently described activatory Siglecs (Siglecs 13-16), which recruit the DNAX-activating protein (DAP) 12 adaptor along with its canonical immunoreceptor tyrosine-based activating motif (ITAM). It appears likely that these are balancing receptors that generate opposing inhibitory and activatory responses, perhaps in response to sialic acid-expressing pathogens.

Known and Putative Functions of the Siglecs

Various lines of evidence indicate that MAG/Siglec-4 is involved in the maintenance of myelin organization and in the inhibition of neurite outgrowth during regeneration after injury. It is also clear that CD22/Siglec-2 functions as an inhibitory component of the antigen receptor complex of B Cells, and is thus involved in regulating the humoral immune

response. While Sn/Siglec-1 appears to mediate various macrophage adhesion events *in vitro* and *in vivo*, it is still somewhat unclear what exactly the functions of these interactions are. This molecule may also assist macrophages in the phagocytosis of sialic acid-expressing pathogen. Relatively little is known about the functions of CD33-related Siglecs. It appears that these molecules are involved in innate immunity. One hypothesis supported by current data is that Siglecs are sensors for pathogens that have sialylated cell surfaces and/or express extra cellular sialidases. The corresponding endogenous function of the inhibitory CD33-Siglecs appears to be to recognize host Sias as self and dampen unwanted innate immune reactivity. Several findings support this notion. For example, mice deficient in Siglec-F (which is normally found on eosinophils) show hyper-eosinophilia and exaggerated allergic responses, and group B Streptococci engage neutrophil Siglec-9 via their sialylated capsules to dampen innate immune responses. Also, human T and B cells express lower levels of CD33-related Siglecs than in great apes and this correlates with increased responses of the human cells to stimuli. It is suggested (but not proven) that the activatory CD33-related Siglecs (13-16) have opposing effects, via their cytosolic ITAM motifs.

Glossary

Alternative σ A σ -factor that can replace the primary σ -factor in response to a particular stress or signal to activate the expression of a defined target regulon.

Promoter DNA sequences necessary for the accurate initiation of transcription by RNA polymerase.

Regulon The set of genes and operons that are regulated by a common factor.

RNA polymerase Enzyme that copies DNA sequences into the complementary RNA sequence.

Introduction

DNA serves as a storehouse for the genetic information of each organism, but is itself a silent repository. Only upon copying of DNA segments into RNA (transcription), and translation into protein, is the genetic potential of each organism (and each cell type in multicellular organisms) able to be realized. For example, our skin, blood, hair, liver, and lung cells all contain the same DNA, yet they have differentiated into functionally distinct cell types based largely on the selective expression of a small subset of the genes contained within each cell. Similarly, comparative genomics has led to the realization that the evolutionary processes that have led to the divergence of humans and mice, for example, have more to do with changes in 'how' genes are regulated than with 'which' genes are actually present in each organism. These examples highlight the importance of gene regulation: those mechanisms that selectively activate and repress different genes depending on cell type and local environment.

Gene Regulation in Bacteria

Most of the principles of gene regulation were first developed from studies of bacterial cells and, in particular, *Escherichia coli*. The first step in gene expression is the transcription of the genetic code from DNA into an RNA copy that usually serves to direct protein synthesis (translation). RNA polymerase (RNAP) is the enzyme that copies (transcribes) DNA into RNA.

In bacterial cells, most gene regulation occurs at the level of transcription. Genes that are expressed are actively transcribed and translated into their corresponding protein products. Conversely, genes that are silent are not copied into RNA. Thus, factors that act to control the activity of RNAP are central to many processes of gene regulation. These regulators include activator proteins, repressor proteins, and σ -factors. In order to appreciate how these factors can control gene expression, the biochemical properties of RNAP and the overall features of the transcription cycle are discussed first, followed by σ -factors.

Bacterial RNA Polymerase and the Transcription Cycle

In bacteria, RNAP is a multisubunit protein complex and contains both a catalytic core enzyme and a specificity subunit known as σ . The core enzyme (containing the β , β' , two α , and the ω polypeptide chains) is able to catalyze the synthesis of RNA directed by a DNA template. Core enzyme associates reversibly with another polypeptide chain, σ , to form the holoenzyme.

RNAP copies particular DNA segments into RNA chains by first initiating RNA synthesis at a promoter site, elongating the RNA chain, and finally terminating transcription (the transcription cycle). In bacteria, many protein-coding genes are organized into cotranscribed groups called operons. In these cases, each messenger RNA (mRNA) product can direct the synthesis of multiple protein products.

The first step in the transcription cycle is promoter site localization and requires the presence of the σ -subunit: only holoenzyme can recognize promoter sites. Promoter sites are typically characterized by defined DNA sequences located just upstream of the site where RNA synthesis begins (designated the +1 site). For example, sequences centered ~10 bp upstream often have a sequence, designated the '-10 region', similar to 5'TATAAT3'. A different conserved sequence (TTGACA) is usually located between 16 and 18 bp further upstream and is designated the '-35 region'. Together, the -35 and -10 sequences provide the necessary information to allow RNAP to identify a promoter. Specific interactions between the σ -subunit of holoenzyme and the -35 and -10 elements allow RNAP to tightly engage the promoter region. Once bound, RNAP interacts with an extended region of DNA, ultimately contacting the DNA over a region of 60 or more base pairs (from -40 to +20).

Once bound at a promoter site, RNAP melts the DNA over approximately one turn of the helix (from about -10 to +2) to expose the template strand of the DNA. The process of converting the double-stranded promoter region DNA into a locally melted structure (called the open complex) requires the action of σ -factor to initiate the melting process and is then driven by the association of the template strand of the DNA with the RNAP active site (comprised largely of the β - and β' -subunits). The open complex is then poised to initiate

synthesis of an RNA chain. The region of DNA strand separation is often referred to as the transcription bubble, to distinguish it from the otherwise double-stranded DNA in the surrounding regions of the genome.

The process of transcription elongation involves the assembly of ribonucleoside triphosphate precursors into an RNA chain containing the sequence complementary to the template DNA. During transcription elongation, the DNA template is threaded through the active site of RNAP and, as a result, the transcription bubble is propagated down the DNA with melting of the DNA occurring as the DNA enters the active site and reannealing of the template occurring as the DNA exits the RNAP. The complex containing the DNA template, RNAP, and the growing RNA chain is often referred to as the ternary complex. As the growing RNA chain emerges from RNAP, it is thought to displace the σ -subunit, and the process of transcription elongation is continued by the core RNAP subunits. Elongating RNAP sometimes associates with additional protein factors known as elongation factors which can modulate its properties. In general, elongation is highly processive: the RNAP that begins an RNA chain continues synthesis until the chain is terminated.

The process of transcription termination, like that of initiation, is critical for the controlled expression of genetic information. At the end of many transcription units the DNA sequence encodes a G:C-rich stem-loop structure in the RNA chain followed by a short region rich in uridine. This structure functions as a transcription terminator and interacts with the core RNAP leading to dissociation of the ternary complex and release of the terminated RNA chain. In other cases, protein factors such as the rho protein can bind to unstructured regions of RNA and trigger transcription termination. Once released by the termination reaction, the core RNAP must rebound to a σ -subunit to reform holoenzyme and thereby complete the transcription cycle.

Since bacteria lack a nuclear membrane, the processes of transcription and translation can be coupled: ribosomes can bind to the mRNA chain as it emerges from RNAP and immediately initiate protein synthesis. Indeed, along actively transcribed genes several RNAP molecules may be simultaneously engaged in RNA chain elongation with each RNA chain in turn bound by one or more ribosomes engaged in protein synthesis.

Biochemical Properties

As expected for a critical component of the transcription apparatus, σ -factors have been highly conserved through evolution. Indeed, σ -factors from one bacterium can function, at least in some cases, with the core RNAP from distantly related species. In general, all σ -factors share certain defining properties. They all bind to the core RNAP, apparently at a common binding site, to form a holoenzyme. The presence of σ -factor determines the sequence of the promoters that can be bound by the corresponding holoenzyme. The σ -subunit, in those cases that have been studied, also plays a role in the initiation of the DNA-melting step that is an obligatory prelude to transcription initiation. Often, although perhaps not always, σ is released from the ternary complex during the process of RNA chain elongation.

Bacterial σ -factors can be divided, based in part on their protein sequences, into two families: the σ^{70} and the σ^{54} families. All bacteria contain at least one member of the σ^{70} family that is required for the transcription of those genes essential for growth under virtually all conditions (so-called 'housekeeping' functions). This is referred to as the primary (or class 1) σ -factor. In addition, most bacteria contain at least one (and as many as 50 or more) alternative σ -factors (Table 1). These factors typically control genes needed for specialized functions that may only be expressed under particular growth conditions. Examples include genes needed for stress responses, motility, sporulation, uptake or transport of specific nutrients, or antibiotic production.

Most alternative σ -factors are structurally related to the primary (class 1) σ -factors and are therefore considered to be members of the σ^{70} family. Some alternative σ -factors (class 2) are very similar to the primary σ -factors but are, however, dispensable for growth. One example is the *E. coli* σ^S (RpoS) protein that becomes active in stationary phase cells. A much larger class of alternative σ -factors are those more distantly related in sequence to the primary σ -factor, and often lacking one or more conserved regions characteristic of the class 1 and 2 proteins. These alternative σ -factors (classes 3, 4, and 5) control a wide range of physiological processes and are often only active under very specific growth conditions. Prominent among these alternative σ -factors are the numerically abundant

Table 1 σ -Factors in *E. coli* and *B. subtilis*

Organism	σ	Gene	Function
<i>E. coli</i>	σ^{70}	<i>rpoD</i>	Housekeeping genes
	σ^H	<i>rpoH</i>	Heat shock
	σ^E	<i>rpoE</i>	Extreme heat shock, periplasmic stress (ECF ^a)
	σ^F	<i>flaA</i>	Flagellar-based motility
	σ^S	<i>rpoS</i>	Stationary phase adaptations
	σ^N	<i>rpoN</i> , <i>glnF</i>	Nitrogen-regulated genes (σ^{54} family)
	σ^{fecI}	<i>fecI</i>	Ferric citrate uptake (ECF)
	σ^A	<i>sigA</i>	Housekeeping genes
	σ^B	<i>sigB</i>	General stress response
	σ^D	<i>sigD</i>	Flagellar-based motility, autolysins
<i>B. subtilis</i>	σ^E	<i>sigE</i>	Sporulation, early mother cell
	σ^F	<i>sigF</i>	Sporulation, early forespore
	σ^G	<i>sigG</i>	Sporulation, late forespore
	σ^H	<i>sigH</i>	Competence and early sporulation
	σ^K	<i>sigK</i>	Sporulation, late mother cell
	σ^L	<i>sigL</i>	Degradative enzymes (σ^{54} family)
	σ^I	<i>ykoZ</i>	Unknown
	σ^{Xpf}	<i>xpf</i>	PBSX regulation
	$\sigma^{YvrI/Ha}$	<i>yvrI</i> , <i>yvrHa</i>	Two-subunit σ , oxalate decarboxylase expression
	σ^X	<i>sigX</i>	Cell envelope modifications (ECF)
	σ^W	<i>sigW</i>	Antibiotic stress responses (ECF)
	σ^M	<i>sigM</i>	Cell wall stresses (ECF)
	σ^V	<i>sigV</i>	Unknown (ECF)
	σ^Y	<i>sigY</i>	Unknown (ECF)
	σ^Z	<i>sigZ</i>	Unknown (ECF)
	σ^{ylaC}	<i>ylaC</i>	Unknown (ECF)

^aECF indicates a factor that is a member of the large extracytoplasmic function family of alternative σ -factors.

extracytoplasmic function (ECF) σ -factors (class 4 proteins) that appear, in general, to control functions related to the cell surface. Finally, many bacteria have alternative σ -factors with a distinctly different protein sequence that defines the σ^{54} family. Unlike members of the σ^{70} family, the σ^{54} -factors form holoenzymes that almost always require adenosine triphosphate (ATP)-dependent activator proteins to activate their target promoters. The prototype of the σ^{54} -family is the *E. coli* σ^{54} (RpoN) protein that is important for nitrogen regulation of gene expression (Table 1). Similar proteins in other bacteria control a variety of functions.

The division of σ^{70} -family members into different structural classes is based in large part on the comparison of their protein sequences. All primary (class 1) σ -factors (and the closely related class 2 factors) have four conserved regions. Region 1 contains an autoinhibitory domain that prevents the free σ -factor from interacting with DNA. This inhibition is relieved when σ associates with core RNAP. Region 2 contains the key determinants for recognition of the -10 promoter element and for initiation of DNA melting. Region 3 functions as a spacer domain between regions 2 and 4 and is important for transcription from some promoters. Region 4 contains the elements that recognize the -35 promoter element and also serves as a site of contact for some transcription activator proteins. Recent advances in the determination of three-dimensional structures for both σ -factors and holoenzyme have made it clear that these protein sequence regions correspond to folded domains in the σ -structure. The two domains that are required for recognition of promoters, domains 2 and 4, are common to all σ^{70} -family members. By contrast, much of domains 1 and 3 are often deleted in alternative σ -factors.

Conventional σ -factors are single polypeptides but two-subunit forms have been recently described. The T4 phage protein gp55 is a truncated highly divergent σ^{70} sigma factor that along with protein gp33 binds to *E. coli* core polymerase and activates transcription of T4 late genes. gp33 is not obviously similar to σ -factor but binds the flap region of the core β subunit and functions analogously to σ region 4. In *Bacillus subtilis*, two proteins called YvrI and YvrHa (Table 1) also bind core polymerase subunits to activate transcription. Both of these proteins are related to σ -factor and represent the first known two-subunit bacterial σ -factor system.

Roles of σ in Gene Regulation

Just as DNA-binding transcriptional repressors and activators can control the activity of RNAP at promoter sites, alternative σ -factors provide a powerful avenue for the activation of specific sets of genes (the σ -factor regulon) during cell differentiation or in response to various stress conditions. The activity of alternative σ -factors can, in turn, be controlled in numerous ways. In some cases, the σ -factor is only synthesized under very specific conditions. In other cases, the σ -factor is synthesized but is maintained in an inactive state by binding to an inhibitory protein (called an anti- σ -factor) or it is synthesized as an inactive precursor protein that only becomes active when an inhibitory peptide is cleaved by proteolysis. Anti- σ -factors are, in many cases, associated with the cell membrane and thereby able to perceive signals from the external environment. In any

event, once the active σ -factor is synthesized or released, it can compete with other σ -factors for binding to core RNAP and thereby redirect some of the RNAP to its cognate target promoters.

Roles for alternative σ -factors in bacterial gene regulation are legion. For example, alternative σ -factors play key roles in the expression of heat shock genes, iron uptake systems, the developmental program of sporulation (in Gram-positive bacteria), synthesis of flagella and chemotaxis machinery, and various stress responses. A summary of the roles of σ -factors in the two best-studied bacterial systems is presented in Table 1.

Phylogenetic Distribution

σ -Factors are always found associated with bacterial RNAP but have been functionally replaced by other proteins in the more complex RNAP characteristic of eukaryotes and Archaea. However, σ -like factors are found in the chloroplasts of photosynthetic eukaryotes which are descended from a cyanobacterium. In contrast to chloroplasts, the transcription apparatus in present-day mitochondria is most similar to certain bacteriophage-encoded, single-subunit RNAPs and is unlike the multisubunit RNAP of either bacteria or eukarya.

Transcription is a process fundamental to all life forms. Core RNAPs from bacteria, archaea, and eukaryotes are related to one another in terms of sequence and structure prompting searches for evolutionary conserved σ -like proteins among these three domains. In bacteria, σ -factor acts as a specificity factor required for promoter recognition by holoenzyme but proteins homologous to σ -factor have not been identified in either the archaea or eukaryotes (with the exception of chloroplast organelles). In the eukaryotes, the initial transcription complex consists of RNAP (PolII), transcription factor IIB (TFIIB), the TATA-box binding protein TBP, and other general transcription factors. In the archaea, polymerase, the TFIIB homolog TFB, and TBP are sufficient for the initiation of transcription. Recent investigation into the structure of the yeast PolII–TFIIB complex suggests that TFIIB may represent the long-sought analog to σ -factor in eukaryotes and archaea. A region of TFIIB (called B ribbon) contacts the flap region of the β subunit as does region 4 of σ -factor. Another region called B linker binds the β' clamp domain as does region 2 of σ . In both yeast and bacteria, these contacts are required for transcription activation. In terms of sequence, overall structure, and the orientation of contacts between σ /TFIIB and core polymerase, it does not appear that σ -factor and TFIIB are evolutionarily related but may instead represent an example of convergent evolution.

Glossary

ATPase A class of enzymes that hydrolyzes adenosine triphosphate (ATP) into adenosine diphosphate (ADP) as an energy source for catalyzing another reaction.

Clamp loader A protein complex that functions to load sliding clamps onto DNA. The prokaryotic clamp loader is gamma complex and the eukaryotic clamp loader is replication factor C (RFC).

DNA polymerase An enzyme whose primary function is to add complementary 2'-deoxyribonucleotides to a DNA strand in a template-directed reaction. In *E. coli*, the primary replicative polymerase is Pol III while the eukaryotic replicative polymerases are DNA polymerases α , δ , and ϵ .

Fluorescence resonance energy transfer (FRET) Also known as resonance energy transfer (RET), this is a mechanism that describes the transfer of energy between two chromophores through nonradiative dipole–dipole coupling.

Processivity In terms of DNA replication, the number of nucleotides added by a DNA polymerase per binding event to the DNA.

Replisome An assembly of proteins and enzymes required for DNA replication.

Sliding clamp A ring-shaped protein complex that serves as a processivity factor for DNA polymerases. The prokaryotic clamp is β -clamp and the eukaryotic clamp is proliferating cell nuclear antigen (PCNA).

Introduction

DNA replication is a process that is essential for both cellular maintenance of the genome and reproduction of this genome from generation to generation. The need to transmit essentially error-free copies of genetic information to succeeding generations has given rise to complex mechanisms for the replication and repair of the genome of even the simplest organisms. Though the specific players within these processes vary from organism to organism, the essential mechanisms are quite similar and in most cases proteins are homologous.

At the most basic level, new DNA is synthesized by DNA polymerases, which are enzymes that incorporate nucleotides to generate a new DNA strand complementary to the original cellular template. These enzymes, along with their accessory proteins that complete the replisome, must possess fidelity and high processivity. Fidelity is achieved both through the base pairing of incoming nucleotides with the DNA template inside the enzyme active site and the proofreading capabilities that allow some DNA polymerases to correct errors. Processivity is achieved by a unique component of the replisome: the sliding clamp. Sliding clamps form ring-shaped complexes that encircle DNA and bind to DNA polymerases. They are fairly well conserved from prokaryotes to eukaryotes and are essential for efficient DNA replication.

Clamp Configuration and Function

Processivity is defined as a polymerase's ability to remain associated with the template and continue adding nucleotides to the growing molecule. It has been shown that polymerases alone, specifically pol III from *Escherichia coli*, can only incorporate tens of nucleotides for each DNA binding event before

dissociating from the template. The addition of a sliding clamp to this reaction confers essentially unlimited processivity to the polymerase, increasing to tens of thousands of nucleotides per binding event.

Solution of the crystal structure of the *E. coli* processivity factor revealed a mechanism by which this protein could so dramatically increase the processivity of the DNA polymerase. Two β monomers form a ring-shaped complex with an inner diameter large enough to encircle duplex DNA. This processivity factor, and others whose structures have since been solved, is now called 'sliding clamps' to illustrate their function. When the polymerase binds a sliding clamp, it is effectively tethered to DNA but capable of moving at rates limited by the rate of DNA synthesis.

Although these clamps vary greatly at the amino acid level for prokaryotes and eukaryotes, structurally they share many characteristics. The clamp from *E. coli*, called the β -clamp and encoded by the *dnaN* gene, is a homodimer of polypeptides each 366 amino acids in length (Figure 1(a)). The sliding clamp in humans and yeast is called proliferating cell nuclear antigen (PCNA). *Saccharomyces cerevisiae* PCNA is a homotrimer of polypeptides each 258 amino acids in length encoded by the *POL30* gene (Figure 1(b)).

Even though these clamps differ in the number of monomers used to construct the active oligomer and differ in amino acid sequences, both clamps are of similar size and shape (Figures 1(c) and 1(d)). As seen in Figure 1, both rings have six globular domains with an inner ring of α -helices and an outer ring of β -sheet clusters. These domains give the structures a pseudo-sixfold axis of symmetry that runs through the center of the clamp.

When the structures are superimposed, the two rings appear to have similar inner and outer diameters (Figure 1(c)) and ring thickness (Figure 1(d)). Both rings are approximately 30 Å

Figure 1 Ribbon diagrams of (a) *E. coli* β -clamp (PDB code 3BEP), (b) *S. cerevisiae* PCNA (PDB code 3K4X). Each monomer is shown in a different color with α -helices represented by coils and β -strands by arrows. A superimposition of the two cartoons in (a) and (b) is shown from a top (c) and side (d) view. In the superimpositions, the β -clamp is shown in blue and PCNA in orange. All images were created using MacPyMol2006.

Figure 2 (a) Ribbon diagram of *S. cerevisiae* PCNA bound to RFC (PDB code 1SXJ). In the ribbon diagram, α -helices are represented by coils and β -stands by arrows. Image was created using MacPyMol2006. (b) Schematic diagram of the clamp-loading reaction in the presence of ATP based upon the structure in (a). Corresponding RFC and PCNA subunits are shown in the same colors as the ribbon diagram, while the DNA is represented by a black and gray helix.

in thickness, which would cover almost a helical turn of the DNA duplex when the clamp is present on DNA. The outer diameters differ slightly with β -clamp at about 80 Å and PCNA at around 90 Å (measurements taken using PDB codes 3BEP and 3K4X with MacPyMol2006). The inner diameter of the rings, approximately 40 Å, provides more than enough space to accommodate a DNA helix, which is 20 Å in diameter.

Clamp/Clamp-Loader Interactions

In solution, sliding clamps generally exist as closed ring structures. To encircle DNA and allow for polymerase tethering, the clamp must be opened and loaded onto DNA. In both prokaryotes and eukaryotes, the clamp is positioned onto DNA by a protein belonging to the AAA+ family of adenosine triphosphatases (ATPases) known as the clamp loader. In *E. coli*, the clamp loader is called the gamma or DnaX complex, and in

S. cerevisiae is called replication factor C (RFC). Both complexes contain an oligomer of five core subunits that serve to bind to the clamp, open it, bind to DNA, and release the closed clamp onto the DNA. This release of the clamp onto DNA is accompanied by adenosine triphosphate (ATP) hydrolysis. These subunits are arranged in a ring somewhat like slices of an orange. Each subunit contains three globular domains that are connected by flexible linkers. The C-terminal domains form a tight ring or collar to hold the subunits in the complex. The complex is more open on the side containing the N-terminal domains, creating a space for DNA to bind. A cartoon schematic of this reaction in the presence of ATP is shown in [Figure 2\(b\)](#).

The crystal structure of the *S. cerevisiae* clamp loader RFC bound to PCNA (PDB code 1SXJ) provides some insight into how these proteins interact and allow for loading of the clamp onto DNA. The individual proteins that comprise RFC are arranged in a spiral manner above the center of the PCNA

ring (Figure 2(a)). DNA modeled into the structure suggests that the subunits spiral with the same pitch as the double helix and that this spiral arranges the ATP-binding sites within RFC so that DNA binding can initiate ATP hydrolysis and the release of the clamp from RFC, loading it onto DNA. Additionally, this spiral may also facilitate the opening of the clamp wherein the clamp adopts a lock washer-like conformation (center cartoon of Figure 2(b)) prior to loading onto DNA. Though this open conformation of the clamp/clamp loader complex has not been trapped in a crystal structure, independent studies utilizing fluorescence energy transfer (FRET) and electron microscopy have shown this conformation to exist *in vitro*.

In the crystal structure shown in Figure 2(a), only three subunits of RFC (those colored purple, blue, and red) make contacts with PCNA. PCNA has three hydrophobic pockets on the surface that would allow for protein–protein interactions, and two of these are bound by RFC. The binding interface between RFC and PCNA is similar to that of other proteins bound to clamps in that hydrophobic loops on two of the RFC subunits (colored purple and red in Figure 2) are inserted into the hydrophobic pockets, providing a stable interaction between the two complexes.

Clamp/Polymerase Interactions

After a sliding clamp is loaded onto DNA, a DNA polymerase binds the clamp and this interaction increases the residence time of the polymerase with the DNA template being copied. DNA polymerases interact with the same hydrophobic pockets on the face of the clamp to which the clamp loaders bind. DNA polymerases and clamp loaders contain a conserved sequence motif that typically contains two aromatic residues, often Phe and Tyr, or a hydrophobic and aromatic residue such as Leu and Phe. These residues bind the hydrophobic pocket. In eukaryotes, this sequence motif is referred to as the PCNA-interacting peptide (PIP). Not only do DNA polymerases bind the clamp, other enzymes such as DNA ligase, flap endonuclease, and chromatin assembly factor, required for DNA replication and repair, also interact with the clamp. These proteins also contain the conserved PIP sequence motif.

During replication, specialized high-fidelity DNA polymerases catalyze the bulk of DNA synthesis, but there are times when other DNA polymerases must take over. One such time is when the replicative polymerase encounters

DNA damage and specialized lesion bypass polymerases take over to extend the DNA past the site of damage. There is evidence that these DNA polymerases make contacts with the clamp in addition to those with the hydrophobic pocket. These other interactions may allow multiple DNA polymerases to bind to a clamp so that when a specialized polymerase is needed, it is physically present within the replisome. In eukaryotic cells, posttranslational modifications of PCNA provide an additional level of regulation of interactions with specialized DNA polymerases and DNA repair proteins.

Clamp/DNA Interactions

Biochemical studies, in addition to the unique ring structure and inner diameter described above for β -clamp and PCNA, provide evidence that these oligomers do indeed encircle DNA to create a tethering system to keep the polymerase bound to the DNA template. Though no structure has been solved to date with all components required for clamp loading (clamp/clamp loader/DNA) or DNA replication (clamp/polymerase/DNA) structures of both β -clamp and PCNA have been solved in complexes with DNA (Figures 3(a) and 3(b), respectively). In both structures, the DNA helix appears to be making strong electrostatic contacts with residues in the α -helices in the center of the clamps. However, it is obvious from Figure 3 that the DNA helix makes quite different contacts with the inner surfaces of the β -clamp and PCNA. Furthermore, biochemical analysis using mutagenesis has implicated additional amino acids as participating clamp/DNA interactions. Together, these results suggest that the DNA helix may adopt many conformations within the clamp ring. There are many positively charged residues within α -helices on the inner surfaces of the clamps, which would allow for strong interactions between the clamp and the negatively charged DNA phosphodiester backbone (Figure 3(c)).

Before these clamp–DNA structures were solved, DNA was modeled through the center of the clamp such that the axis of the helix was perpendicular to the plane of the ring. X-ray crystallographic, electron microscopy, and mutagenesis studies have indicated that this assumption is unlikely to be true. Mutagenesis studies have found specific amino acids within the center of the ring that are necessary for clamp–DNA interactions. An archaeal sliding clamp/clamp loader/DNA complex structure has been solved in which the clamp is in an open conformation with the DNA bound near the open

Figure 3 Ribbon diagrams of (a) β -clamp (PDB code 3BEP) and (b) PCNA (PDB code 3K4X) bound to a DNA duplex. In each diagram α -helices are represented by coils and β -strands by arrows. DNA is shown as a sticks with the phosphodiester backbone in orange and the bases modeled as blue and green sticks. PCNA (PDB code 3K4X) surface charge representation (c) is shown in the same orientation as (b). Red indicates negative charge, blue positive charge, and white hydrophobic areas. Images were created using MacPyMol2006.

interface at an angle. In the crystal structures described above, it appears that DNA makes strong electrostatic interactions with the clamp that could potentially inhibit the rate of DNA synthesis when a polymerase is bound. It has been suggested that polymerase binding may alter the angle between the axis of DNA and the clamp so that the clamp can slide freely along DNA, limited only by the rate of synthesis itself. Taken together, the data suggest that the clamp actually functions by making an angle of 20° with the axis of the clamp, which seems to provide not only a strong interaction with the DNA but also a level of regulation in terms of loading the clamp and its subsequent function during replication.

Processivity Factors in Other Species

Though β -clamp (from *E. coli*) and PCNA (from *S. cerevisiae* and *Homo sapiens*) are the most commonly studied sliding clamps, processivity factors have been found and characterized in many other species as well. Some of these factors, such as a clamp involved in eukaryotic DNA damage response and clamps from various species of archaea and bacteriophages, have structures similar to either β -clamp or PCNA while others, such as that utilized by herpes simplex virus (HSV), adopt quite different structures. Though there is little to no sequence homology between them, each of these processivity factors shares some structural and functional characteristics with β -clamp and PCNA.

H. sapiens PCNA

PCNA from *H. sapiens* is a homotrimer of subunits encoded by the PCNA gene with each subunit 261 amino acids in length. *H. sapiens* PCNA has a structure very similar to that of *S. cerevisiae* PCNA, as shown by the superimposition of the two structures in Figure 4(a). Both rings are homotrimers and in addition to similar shape also have almost identical inner and outer diameters, thickness, and surface-charge distribution. In spite of the lack of sequence homology, the three-dimensional structural similarity between these two clamps

has allowed for studies involving the *S. cerevisiae* clamp, which is generally easier to work within the laboratory from a genetic standpoint, to provide insight into the machinery involving the *H. sapiens* sliding clamp.

H. sapiens 9–1–1 Clamp

In *H. sapiens* and yeast, a second clamp, the 9–1–1 complex, has been identified. This clamp is involved in the cellular response to DNA damage (Figure 4(b)). Though this clamp shares structural similarities in size and surface-charge distribution with PCNA (compare the structures in Figures 4(a) and 4(b)), it is a heterotrimer composed of the proteins RAD9 (encoded by the RAD9 gene and 396 amino acids in length), RAD1 (encoded by the RAD1 gene and 286 amino acids in length), and HUS1 (encoded by the HUS1 gene and 283 amino acids in length). The homologous yeast clamps are also heterotrimers, but the structures have not yet been solved. Even though the amino acid sequences and structural organization (homotrimer vs. heterotrimer) of PCNA and the 9–1–1 clamp are radically different, the two adopt very similar tertiary structures.

Archaeal Processivity Factors

Although species within the domain Archaea were once grouped with bacteria under the name archaebacteria, early genome-sequencing projects revealed that at the genomic level these species had more in common with eukaryotes than prokaryotes, specifically with respect to their DNA replication machinery. Some archaea have been found to have two origins of replication within their genome, which is not commonly seen in prokaryotic organisms. Additionally, similarities exist between proteins essential for DNA replication, including the DNA polymerase, helicase, clamp loader, and sliding clamp.

Though β -clamp from *E. coli* is a homodimer, PCNA molecules from archaea adopt different structural assemblies. For example, PCNA from *Haloferax volcanii*, a species of archaea that exists in extreme saline environments like the Dead Sea or the Great Salt Lake, is composed of a homotrimer of subunits (Figure 5(a)). By contrast, PCNA from *Sulfolobus solfataricus*, a species of archaea found in volcanic hot springs that utilize sulfur during metabolism in the absence of an oxygen source, is a heterotrimer (Figure 5(b)). These architectures differ greatly from β -clamp from *E. coli* but *H. volcanii* PCNA is assembled much like *S. cerevisiae* and *H. sapiens* PCNA (compare Figure 5(a) with Figure 4(a)), while *S. solfataricus* is assembled like the 9–1–1 clamp from *H. sapiens* (compare Figure 5(b) with Figure 4(b)).

Even though there are differences between the clamps from prokaryotic, archaeal, and eukaryotic systems with regard to the number and type of subunits, each adopts the same overall shape and size. The crystal structure for PCNA from two additional archaeal species, *Archaeoglobus fulgidus* (PDB code 1RWZ) and *Pyrococcus furiosus* (PDB code 1GE8), has also been solved. These two, not shown in Figure 5, are homotrimers of similar characteristics to PCNA from *S. cerevisiae*.

Additionally, each of these rings show similar charge distribution (*S. cerevisiae* (Figure 3(c)), *H. volcanii* (Figure 5(e)),

Figure 4 (a) Superimposition of ribbon diagrams for PCNA from *S. cerevisiae* (PDB code 3K4X) and *H. sapiens* (PDB code 1AXC), shown in green and blue, respectively. Ribbon diagram (b) of the checkpoint clamp (known as 9–1–1) from *H. sapiens* with RAD9 shown in pink, RAD1 in yellow, and HUS1 in cyan. The *in vivo* structure of this clamp may adopt a different shape as the Rad9 subunit has been truncated for ease of expression and crystallization. In each diagram α -helices are represented by coils and β -strands by arrows. Images were created using MacPyMol2006.

Figure 5 Ribbon diagrams of the PCNA structure from (a) *H. volcanii* (PDB code 3IFV) and (b) *S. solfataricus* (PDB code 2NTI) and the processivity factors (c) UL42 from HSV shown in orange (PDB code 1DML) and a *S. cerevisiae* PCNA monomer shown in blue (PDB code 1PLQ) and (d) gp45 from T4 bacteriophage (PDB code 1CZD). In the ribbon diagrams, each monomer is a different color and α -helices are represented by coils and β -strands by arrows. Surface-charge representations are given below each ribbon diagram (e)–(h) with the protein in the same orientation. For the charge distributions, red indicates negative charge, blue positive charge, and white hydrophobic areas. See text for more details. Images were created using MacPyMol2006.

S. solfataricus (Figure 5(f)) with the inner ring of α -helices having a positive charge that allows for interactions with the negatively charged DNA as it threads through the center of the clamp. The most divergent of the three as far as charge distribution is the *H. volcanii* PCNA. The complex appears to have a much lower concentration of positive charge within the center of the ring (this cluster of positive charge is generally considered to be a hallmark of clamp structure) when compared to other sliding clamps and also has a higher distribution of negative charge throughout the surface of the ring. It has been proposed that bound cations within the solvation shell may serve to coordinate interactions between DNA and the clamp. These differences are likely due to adaptations necessary for survival within a highly saline environment.

Viral Processivity Factors

Most of the processivity factors discovered thus far adopt a ring shape with a pseudo-six-fold axis of symmetry due to domain organization. Interestingly, the processivity factors from some viruses, specifically HSV and Epstein–Barr virus, share some structural features with eukaryotic clamps but have a different mechanism of action. These processivity factors are termed polymerase associated. They do not form ring-shaped protein complexes even though their overall structures are similar to that of a PCNA monomer. The structure of the HSV processivity factor UL42 (orange ribbon diagram) is shown in Figure 5(c) bound to a short segment of the HSV DNA polymerase (yellow ribbon diagram). For the purpose of comparison, the structure has been shown next to that of a *S. cerevisiae* PCNA monomer (blue ribbon diagram). From this figure, it appears that the HSV processivity factor is a two-domain structure with one surface predominantly α -helix and the opposite β -sheet, much like each of the sliding clamp monomers for the structures discussed previously. Though only a small fragment of the associated polymerase has been crystallized, it appears that the polymerase binds to the β -strand domain of UL42 leaving the α -helical surface free to interact with the DNA during replication, as has been observed for sliding clamps. The surface-charge

distribution (Figure 5(g)) also suggests that the α -helices interact with the DNA, as there is a concentration of positive charge on this face of the protein. This structure and biochemical data have shown quite different interactions between DNA and the processivity factor compared to those seen for sliding clamps; however, the overall surface-charge distribution and separation of α -helical and β -strand domains to create unique binding sites remain constant characteristics when compared to typical sliding-clamp processivity factors.

Bacteriophage Processivity Factors

Finally, the structures of processivity factors from bacteriophages have also been solved. The sliding clamps, gp45, from bacteriophage T4 and RB69 adopt a ring structure slightly different from other sliding clamps described thus far. These sliding clamps are homotrimers, like various PCNA molecules, but they lack the pseudo-six-fold axis of symmetry. Instead, they adopt a very strong threefold axis of symmetry that runs through the center of the ring (T4 gp45 shown in Figure 5(d)). In spite of differences in shape, the inner and outer diameter and thickness values are similar to those seen for *S. cerevisiae* PCNA. Additionally, the ring also has the inner ring of positive surface charge that has been observed in other ring structures (Figure 5(h)). Solution studies have revealed that one interface of the bacteriophage T4 clamp is opened, but not far enough to allow the clamp to bind DNA on its own. This clamp must still be loaded onto DNA by the activity of a clamp loader.

Conclusion

Although the replisomes from prokaryotes, archaea, and eukaryotes differ in some of their basic structure and individual components, the sliding clamps that serve to tether the polymerase to the template DNA are quite similar in structure and function. The clamps from *E. coli* and *S. cerevisiae* are almost identical in size and show similar mechanisms for binding to their respective clamp loaders and polymerases and to DNA

templates. Additionally, clamps and processivity factors from other species show much similarity in architecture, size, and shape, and structural features necessary for activity. This conservation suggests that processivity factors, in particular those that form sliding-clamp structures, have evolved as a necessary element for efficient DNA replication.

Glossary

Cytoskeleton A dynamic network of filaments, microfilaments, microtubules, and intermediate filaments.

Effector proteins Proteins that bind preferentially to the guanosine triphosphate (GTP)-bound form of small guanosine triphosphatases (GTPases) and facilitate the biological response of small GTPases.

GTPase-activating proteins Negative regulatory proteins that accelerate the intrinsic GTP hydrolysis activity of small GTPases.

Guanine nucleotide exchange factors Regulatory protein that accelerates the intrinsic guanosine diphosphate (GDP)/GTP exchange activity of small GTPases.

Guanine nucleotides Amine nucleotide bases composed of a guanine moiety attached to one (guanosine monophosphate, GMP), two (GDP), or three (GTP) phosphate groups.

Guanosine triphosphatases (GTPases) High-affinity GDP-, GTP-binding, and GTP-hydrolyzing proteins that act as molecular switches and timers that

cycle between inactive GDP-bound and active GTP-bound states.

Isoprenylation Posttranslational, covalent modification of proteins at carboxyl-terminal cysteine residues, by either C15 farnesyl or C20 geranylgeranyl isoprenoid lipids.

Kinase An enzyme with phosphorylating activity on either proteins or lipids.

Ras Identified originally as the protein encoded by retrovirus genes responsible for the oncogenic activities of the Harvey and Kirsten murine sarcoma RNA tumor viruses. They represent cellular rat genes transduced into the virus genome from their infected host during infection, leading to formation of rat sarcomas.

Superfamily, family, and subfamily Small GTPases are classified into hierarchical phylogenies on the basis of structural, sequence, and functional similarity between members. Members of the Ras family share ~50% amino acid identity with the four Ras proteins, whereas members of the Rho family, Rab family, and other Ras superfamily GTPases share ~25–30% amino acid identity with Ras proteins.

Identification and Classification of Small Guanosine Triphosphatases

The first and prototypical small guanosine triphosphatases (GTPases) were identified as the proteins encoded by the retrovirus oncogenes of the Harvey and Kirsten rat sarcoma (Ras) viruses (Figure 1). Since these initial discoveries, over 150 mammalian proteins have been identified that show varying degrees of both amino acid sequence and structural similarity with Ras proteins. Small GTPases were identified initially by a variety of approaches, some fortuitously (e.g., Rho), some by yeast genetic studies (e.g., Rabs), and others by nucleic acid sequence homology (e.g., Ral and Rap) or guanosine triphosphate (GTP)-binding activities. *In silico* database searches have identified additional members. These Ras superfamily proteins are further divided into families according to sequence identity and cellular function. The five major branches are the Ras, Rho, Rab, Arf, and Ran families (Figure 2). Small GTPases are well conserved in evolution, with structural and functional homologs of many of the mammalian proteins found in yeast, flies, worms, and plants. Interestingly, no Ras family proteins are found in plants.

In addition to GTPase activity, a feature of many small GTPases is lipid modification important for subcellular localization at membranes. Members of the Ras, Rho, and Rab families are modified by either the C15 farnesyl or C20 geranylgeranyl isoprenoid lipid (Figure 3). Protein prenylation is signaled by C-terminal sequences. For Ras and Rho small

GTPases, this lipid modification occurs at a particular motif, the CAAX tetrapeptide motif, consisting of a cysteine followed by two aliphatic amino acids, and a terminal X residue that determines whether the protein will be modified by farnesyltransferase (X=S, M, Q, and A) or geranylgeranyl transferase-I (X=L, F). Some Ras and Rho family small GTPases also are posttranslationally modified by a C16 palmitate fatty acid on cysteines adjacent to the CAAX motif. Rab proteins possess cysteine-containing C-terminal motifs (Figure 3) that signal geranylgeranyl isoprenoid posttranslational modification by a third prenyltransferase, geranylgeranyltransferase-II. Arf proteins are cotranslationally modified by the C14 myristate fatty acid at the N-terminus. Lipid modification facilitates the association of small GTPases with specific membrane compartments and typically is critical for protein function. Ran and the Rho family members RhoBTB1 and RhoBTB2 are unusual among small GTPases as they do not undergo any lipid modification.

Guanosine Diphosphate/GTP Structure and Regulation

Small GTPase Structure

The structure of the H-Ras protein has been determined in many forms and has established the general rules and requirements for all small GTPases. The H-Ras structure was the first to be solved, and subsequent structural studies of other Ras

Figure 1 Small GTPases function as GDP/GTP-regulated molecular switches. Intracellular GDP and GTP are at low mM levels, and small GTPases have low pM binding affinities for guanine nucleotides. Hence, small GTPases are persistently guanine nucleotide bound. The intrinsic GDP/GTP exchange activity is accelerated by guanine nucleotide exchange factors (GEFs) to promote formation of the active GTP-bound protein, whereas GTPase-activating proteins (GAPs) stimulate the intrinsic GTP hydrolysis activity leading to inactive, GDP-bound protein and the release of free phosphate (P_i). Guanine nucleotide dissociation inhibitors (GDIs) prevent nucleotide exchange as well as GAP stimulation. Small GTPase activation commonly is mediated by a signal input that triggers GEF function. The GTP-bound GTPase displays higher affinity for downstream effector targets, leading to induction of various cellular responses.

Figure 2 Small GTPases of the Ras superfamily. Five main families comprise the Ras superfamily, and proteins are organized according to sequence and functional similarity. Representative subfamily members are listed for each, with the total number of human family members indicated below the family name.

superfamily members have demonstrated a conserved structural fold (designated the G domain) shared among all GTPases, but with variations in features for different small GTPase family members (Figure 4).

All small GTPases possess a core G domain that is characterized by a set of canonical sequence elements shared with

other GTPases. The G domain contains the GTP-binding pocket and GTP hydrolytic machinery, although some proteins are GTPase deficient due to key sequence divergence in this domain. A significant observation from Ras structural studies was the primary difference between the guanosine diphosphate (GDP)- and GTP-bound forms, which is localized to

Figure 3 Posttranslational modification by prenylation is important for the function of some small GTPases. Members of the Ras and Rho family of small GTPases terminate with CAAX tetrapeptide sequences that signal a series of posttranslational modifications important for membrane binding and function. For example, Ras proteins are synthesized initially as inactive, cytosolic proteins. Ras proteins are first modified by farnesyltransferase (FTase) which catalyzes the covalent addition of a C15 farnesyl isoprenoid (F) lipid to the cysteine residue of the CAAX motif. This is followed by Rce1-mediated proteolytic removal of the -AAX peptide and Icmt-catalyzed carboxymethylation (O-Me) of the now terminal farnesylated cysteine residue. Rho GTPases undergo the same series of modifications, with the first step, addition of the geranylgeranyl isoprenoid (GG), catalyzed by geranylgeranyltransferase I (GGTase-I). RhoGDIs recognize the prenylated form of Rho GTPases and prevent their association with membranes, thus leading to Rho GTPase inactivation.

Figure 4 Small GTPase functional domains. Members of the small GTPase family share sequence similarities that define distinct functional domains. The G domain is comprised of a set of five conserved sequence elements involved in binding phosphate/ Mg^{2+} (PM) or the guanine base (G). The switch I and II (SI, SII) regions change in conformation during GDP/GTP cycling and contribute to preferential effector (E) binding to the GTP-bound state. For Arf, the N-terminus changes conformation during GDP/GTP cycling, with GTP-binding exposing the myristate to facilitate membrane binding. By contrast, the C-terminus of Ran changes conformation during GDP/GTP cycling. Ras, Rho, and Rab membrane association is facilitated by lipid modification of C-terminal sequences that include the CAAX motif (for Ras and Rho proteins) as well as sequences upstream of this sequence. Rho GTPases possess additional sequences (Rho insert) not found in other small GTPases. Some small GTPases contain additional N- or C-terminal sequence extensions.

two regions, termed switch I (residues 32–38) and switch II (residues 59–67). Similar switch-I and switch-II conformation changes also have been identified for the GDP- and GTP-bound states of other small GTPases.

Switch I and switch II show sequence divergence between families, although the loop-like structures of each are conserved. In addition to reflecting the nucleotide-bound state of the small GTPase, the switch regions also are involved in the interaction of small GTPases with effectors and regulatory molecules. Sequence divergence in the switch regions of different proteins contributes to the selectivity of small GTPases for various binding partners.

Members of the Rho family of small GTPases possess a unique structural feature that is absent in all other small GTPases. The Rho family proteins contain an insertion of ~13 amino acids, called the insert region, positioned between Ras residues 122 and 123, which form a surface-exposed loop (Figure 4). The primary sequence and secondary conformation of this insert region varies within the Rho family. Although the conformation of the insert region is not influenced by nucleotide binding, there is evidence that it is involved in effector interaction and activation.

Other small GTPases possess additional N- or C-terminal extensions important for function. For example, Arf family proteins contain an N-terminal extension necessary for insertion into and interaction with the membrane, whereas Ran has an elongated C-terminus that is crucial for its function in nuclear transport (Figure 4).

The Small GTPase Cycle and Its Regulation

The 'on' and 'off' switching nature of small GTPases is best described as a GDP/GTP cycle (Figure 1). The intrinsic processes of nucleotide exchange and GTP hydrolysis occur at basal rates characteristic to each small GTPase. Two classes of regulatory proteins act to increase the rate of these processes by several orders of magnitude: guanine nucleotide exchange factors (GEFs) increase the rate of nucleotide exchange, and GTPase-activating proteins (GAPs) stimulate GTP hydrolysis. The Rho and Rab families of small GTPases have additional regulatory protein binding partners called guanine nucleotide dissociation inhibitors (GDIs). Among all small GTPases, evidence indicates that only RhoBTB1 and RhoBTB2 have non-functional GTPase domains, despite sequence homology with the GTPase domains of other Rho family members.

Guanine Nucleotide Exchange Factors

GEFs constitute the primary mechanism for regulated activation of small GTPases and their downstream effects *in vivo*. They are responsible for promoting the exchange of free cytosolic GTP for bound GDP. Exchange is not an active process; rather, GEFs act to facilitate the replacement of one nucleotide with another, and it is the ~10-fold molar excess of cytosolic GTP that favors the binding of GTP rather than GDP. Furthermore, the binding of GTP during the exchange reaction weakens the affinity of the GEF for the small GTPase and induces subsequent dissociation. The binding of GDP does not cause dissociation of the complex.

GEFs have been identified for many small GTPases. They are related by shared sequence of the exchange motif and exhibit selectivity for GTPase binding partners within, but not between, different GTPase families. For example, the two largest classes of GEFs are the CDC25 homology domain-containing proteins which act on Ras family members, and the Dbl homology domain-containing proteins which act on Rho family members. Structurally distinct GEF have been identified for Rab, Arf, and Ran family proteins. As with other smaller classes of GEFs, the structures of the catalytic exchange motifs of RhoGEFs and RasGEFs are unrelated. However, the overall mechanism of exchange appears to be universal; binding of the GEF sufficiently perturbs the phosphate-binding site within the GTPase domain to allow the insertion of GTP and displacement of GDP.

Different GEFs Are Activated by Different Signaling Cascades

The various GEFs identified for Ras and Rho family members overwhelmingly outnumber their respective GTPase binding partners. At least 30 Ras family GEFs have been characterized to date, and more than 80 RhoGEFs have been identified. As a result, many Ras and Rho GTPases can be activated by multiple GEFs. For example, at least 24 Dbl family RhoGEFs have been reported to activate RhoA. The general understanding of these disparities in numbers is that this provides a mechanism whereby divergent signaling cascades may activate the same small GTPase. GEFs that share a common small GTPase substrate often diverge in the sequences that flank the GEF catalytic domain. These sequences commonly contain a large number of different protein–protein and protein–lipid domains or recognition motifs that allow them to respond to a wide variety of signals. In this manner, a common small GTPase can serve as an intracellular convergence point for multiple divergent extracellular cues (Figure 5). By contrast, only a handful of GEFs have been identified for Rab family proteins, the largest family of small GTPases. RabGEFs also possess significant sequence diversity, with at least six distinct families identified. The single Ran small GTPase is regulated by only one RanGEF.

Activation of GEFs occurs by a variety and frequently a combination of mechanisms, including protein–protein interaction, posttranslational modification, second-messenger-induced activation, and membrane recruitment. The classical model of small GTPase activation is that of Ras and its GEF, son of sevenless (Sos). Upon extracellular ligand activation of a receptor protein tyrosine kinase (e.g., the epidermal growth factor receptor, EGFR) and autophosphorylation of specific intracellular tyrosine residues in the cytoplasmic domain of EGFR, an adaptor protein, Grb2, is recruited to specific phosphotyrosine sites via its Src homology 2 (SH2) domain (Figure 5). Grb2, in turn, interacts via Src homology 3 (SH3) domain interaction with specific proline-rich sequences on Sos, and recruits Sos to the membrane to activate resident Ras family proteins.

Membrane localization of the GEF, in proximity with its membrane-bound GTPase targets, is a critical step in the activation process of small GTPases. Scaffolding proteins such as Grb2 represent one mechanism for the targeted recruitment of

Figure 5 Ras guanine nucleotide exchange factors are activated by diverse upstream signals. Extracellular signals promote Ras activation by stimulating the activity of different RasGEFs. All RasGEFs share a common CDC25 homology domain that catalyzes nucleotide exchange on various Ras family small GTPases (Ras, Rap, R-Ras, and Ral). However, they diverge in sequence flanking the catalytic domain and are characterized by distinct interaction domains/motifs that link their activation to specific upstream signaling events. Examples of various GEF activation mechanisms are shown. RasGEFs can be activated by phospholipase C-catalyzed formation of membrane-bound diacylglycerol (DAG) and DAG binding to the C1 domain of RasGRP1-4; calcium influx and calmodulin binding to the IQ domain of RasGRF; Grb2 adaptor binding to proline-rich (PXXP) motifs in Sos via its tandem SH3 domains; and activated Ras-GTP binding to Ras Association (RA) domains of RalGEFs.

GEFs to the plasma membrane and other intracellular lipid compartments. Transiently produced membrane lipids including diacylglycerol (DAG) and phosphatidylinositol 3,4,5-trisphosphate (PIP_3) are other common mechanisms for controlling localized GEF, and likewise small GTPase, activity within the cell (Figure 4).

An emerging model of GEF activation, which appears to be common to several RhoGEFs of the Dbl family, is the relief of intramolecular interactions that constrain the protein in an inactive conformation. This has been shown best for the Dbl family RhoGEF Vav1 in which phosphorylation leads to the conformational relief of autoinhibition by the N-terminal fragment. Following phosphorylation, the active conformation of Vav1 is available to interact with cognate small Rho GTPases. That N-terminal truncation of sequences upstream of the Dbl homology domain of other RhoGEFs creates constitutively activated variants supports the generality of this auto-inhibitory mechanism. Additional mechanisms of RhoGEF activation include activated Ras binding to a Ras-binding domain in Tiam1 or adenomatous polyposis coli (APC) tumor suppressor binding to Asef.

GTPase-Activating Proteins

The intrinsic hydrolysis rate of the majority of small GTPases is surprisingly slow and sufficiently slow to limit significantly the efficiency of GTPase-mediated signal transduction. In the absence of modulators, signals not only would be transduced too slowly, but also the GTPase 'on' state would persist for an excessive period of time. Whereas GEFs act to accelerate small GTPase activation, GAPs serve to accelerate the hydrolytic activity of the small GTPase and therefore make signaling more efficient and dynamic (Figure 1).

As with GEFs, the number of GAPs which act upon Ras and Rho small GTPases exceeds the number of small GTPase targets. Ras proteins are regulated by six distinct RasGAPs, and there are 67 human RhoGAPs. GAPs for small GTPases are not

conserved in sequence among the small GTPase families and have different mechanisms of action. In general, however, GAPs serve to stabilize the hydrolytic machinery of the small GTPase.

Similar to GEFs, many GAPs are also multidomain proteins. Beyond the GAP catalytic domain, the proteins frequently possess regulatory elements important for interaction with proteins (e.g., Rap1GAP activation by Gi), lipids (e.g., ARAP ArfGAP activation by PIP_2 and PIP_3), and second-messenger molecules (e.g., CAPRI Ras/RapGAP membrane recruitment by Ca^{2+}). Some more complex proteins contain both GEF and GAP domains (e.g., Bcr has both RhoGEF and RhoGAP activity), and some contain multiple domains of the same type but with different selectivity (e.g., Sos has two distinct GEF catalytic exchange domains, a CDC25 homology domain for Ras and a DH domain for Rho proteins).

Guanine Nucleotide Dissociation Inhibitors

GDI have been identified for Rho and Rab proteins. Two distinct negative regulatory functions have been ascribed to GDIs. First, they bind to and mask the isoprenoid lipid modification in the C-terminus of the small GTPase, thus preventing the association of the small GTPase with membranes (Figure 3). Second, in general, GDI binding perturbs GAP and GEF regulation, preventing small GTPase activation. Three RhoGDIs and one RabGDI have been described and can recognize multiple family members. The mechanisms of regulation of GDI activity are unclear but may involve phosphorylation.

Genetic Deregulation of Small GTPases

Normal eukaryotic cells rely on the activity of small GTPases to orchestrate basic biological processes, and the innate mechanisms of GEF, GAP, and GDI regulation, in most cases, maintain a tightly controlled level of GTPase activity sufficient for these

purposes. Genetic deregulation, however, can lead to aberrant GTPase signaling, and, in this manner, overly active small GTPase activity contributes to many human cancers and developmental disorders.

The genetic mechanisms that underlie deregulation of GTPase biology are of a variety of types, the most common being mutational activation of RAS, the most frequently mutated oncogene in human carcinomas (33% of all human cancers). The mutated Ras proteins found in human cancers contain single amino acid substitutions primarily at glycine 12 (G12), glycine 13 (G13), or glutamine 61 (Q61), which render the proteins insensitive to GAP stimulation. These GTPase-deficient mutants are persistently GTP-bound in the absence of upstream stimulation and consequently cause deregulated effector activation. The experimental introduction of analogous mutations at residues corresponding to Ras G12 or Q61 also renders other small GTPases GAP insensitive and constitutively activated. Some wild-type small GTPases, however, possess naturally occurring sequence variation at or near these two residues and are persistently GTP-bound proteins (e.g., RhoE/Rnd3 and Rac1b).

Elevated small GTPase activity in pathological conditions also occurs by indirect genetic mechanisms including altered gene expression of wild-type proteins (e.g., RhoC) or their regulatory proteins, alternative gene splicing (e.g., Rac1b, a constitutively GTP-bound variant of Rac1), and amplified upstream signaling processes. Multiple upstream activators of small GTPases drive oncogenesis by either mutational activation (e.g., EGFR) or protein overexpression (e.g., Vav, EGFR, and P-Rex1).

Genomic loss of negative regulators of small GTPase activity promotes aberrant signal transduction as well, as is the case with the loss of the RhoGAP DLC-1 in liver and other cancers. Paradoxically, increased expression of some ArfGAPs and RhoGDIs has been observed in some cancer types, suggesting that aberrant levels, high or low, of some small GTPase regulators can contribute to pathologically relevant GTPase activity. Thus, while GDP/GTP regulation is the major mode of

small GTPase regulation, for some GTPases, regulation by other mechanisms is also important.

Diverse Biology and Function of Small GTPases

Despite their strong structural and biochemical similarities, small GTPases facilitate a remarkably divergent spectrum of cellular functions. This diversity is accomplished by the input signals that regulate the distinct GAPs and GEFs to modulate GDP/GTP cycling, and by the unique set of effectors that are recognized by the GTP-bound forms of small GTPases within and between families, resulting in many different cellular responses.

Ras Proteins as Signaling Nodes and Regulators of Cell Proliferation

The frequent mutation of Ras proteins in human cancers has made these small GTPases the most intensely studied and best characterized. Recently, mutational activation of Ras has also been found in several human developmental disorders (e.g., Noonan syndrome, Costello syndrome, and cardio-facio-cutaneous syndrome). Ras proteins serve as signaling nodes, where a wide diversity of extracellular signals such as growth factors (epidermal growth factor and platelet-derived growth factor), hormones (insulin), cytokines (interleukin-1), and the extracellular matrix proteins (via integrins) converge on and cause activation of Ras. Activated Ras in turn interacts with and regulates the activities of downstream effectors with highly divergent biochemical functions. Recent reviews have provided detailed discussions of Ras effector utilization. Therefore, we have highlighted various themes.

The Raf serine/threonine kinases are important effectors of Ras and facilitate activation of the extracellular signal regulated kinase (ERK) mitogen-activated protein kinase cascade (Figure 6). Ras induces Raf activation by promoting

Figure 6 Ras effectors mediate diverse signaling outcomes. Activated, GTP-bound Ras can bind and regulate functionally diverse downstream effector targets. These include activation of a protein kinase cascade (Raf), activation of the PI3K lipid kinase, and activation of PLC epsilon and the production of second messengers (DAG and calcium). Several Ras effectors are GEFs that activate other members of the Ras superfamily, including Rab5 (Rin1-3), Ral (RalGEFs), and Rac (Tiam1). Thus, Ras functions as a signaling node, where diverse signals converge and cause its activation (Figure 5) and induction of diverse downstream cytoplasmic signaling pathways.

association of the normally cytosolic Raf with the plasma membrane where a complex set of events, including protein phosphorylation, activates Raf kinase function. Activated Raf then phosphorylates and activates the MEK1 and MEK2 dual-specificity protein kinases, which phosphorylate and activate ERK1 and ERK2. Activated ERK translocates to the nucleus and phosphorylates a variety of targets that include Ets family transcription factors. The Raf–MEK–ERK kinase cascade contributes significantly to the growth-regulatory functions of Ras. The mutational activation of one Raf protein (B-Raf) in human cancers and the mutational activation of Raf and MEK in developmental disorders support the importance of this effector pathway in promoting the consequences of Ras activation in these diseases.

The second best-characterized class of Ras effectors is the phosphatidylinositol 3-kinases (PI3K), a family of lipid kinases (Figure 6). A major activity of PI3K is the conversion of membrane-associated phosphatidylinositol 4,5-bisphosphate (PIP₂) to phosphatidylinositol 3,4,5-trisphosphate (PIP₃). PIP₃ in turn can regulate the activity of a diverse range of targets, including activation of the Akt serine/threonine kinase and RacGEFs, via PIP₃ interaction with pleckstrin homology domains present in these proteins. Mutational activation of p110 alpha, a catalytic subunit of PI3K, is seen commonly in human cancers.

One significant theme that has emerged is that a number of Ras effectors are GEFs, thereby linking Ras activation with regulation of other small GTPases (Figure 6). First, there is a family of RalGEFs that binds GTP-bound Ras and promotes activation of RalA and RalB, members of the Ras family of small GTPases. Second, the Ras effector Rin1 functions as a GEF for Rab5, thus linking Ras activity with Rab-regulated vesicular trafficking. Third, Ras binds and activates Tiam1 which functions as a GEF for Rac. Fourth, Ras binds phospholipase C epsilon, which also contains a CDC25 homology Ras GEF catalytic domain that activates the Rap small GTPases, members of the Ras family.

While Ras GTPases function as positive regulators of cell proliferation, some small GTPases appear to possess opposing functions and may operate as tumor suppressors rather than oncogene proteins. This includes Rerg, NOEY2/ARH1 and Rig. Thus, while these proteins share significant sequence and biochemical functions with Ras, clearly their effector functions are quite distinct. Additionally, whereas mutational activation of Ras proteins is associated with oncogenesis, it is the loss of gene expression of these Ras-related proteins that accounts for their loss of function in tumor cells.

Rho Family Proteins and Actin Cytoskeletal Organization, Cell Morphology, and Cell Movement

Similar to Ras proteins, Rho family small GTPases also function as signaling nodes activated by diverse extracellular signals. Perhaps the best-characterized cellular function of these proteins is their regulation of actin cytoskeletal organization, which in turn influences cell morphology, cell–matrix and cell–cell interactions, cell polarity, and cell movement. For example, RhoA causes actin stress fiber formation, Rac causes actin accumulation at the leading edge of a motile cell and lamellipodia formation, and Cdc42 promotes actin microspikes and filopodia formation. These changes in actin organization can influence cell shape, cell motility, and cell–cell interactions. Rho family members also participate in signaling events leading to changes in gene transcription and cell-cycle progression.

Small GTPases and Membrane Trafficking

Rab proteins constitute the largest subfamily of small GTPases with more than 60 mammalian members. Rab proteins are involved in the modulation of specific steps in eukaryotic membrane trafficking in the secretory and endocytic pathways. Arf small GTPases are also involved in the regulation of cytoplasmic vesicular trafficking. By contrast, Ran is a regulator of nucleocytoplasmic transport. The regulation of the GDP/GTP cycle is critical for the transport functions of these small GTPases.

Glossary

cas CRISPR associated.

CRISPR Clustered regularly interspaced short palindromic repeats.

crRNA CRISPR RNA – processed transcript of CRISPR locus.

HGT Horizontal gene transfer – exchange of DNA between different species.

miRNA MicroRNA – specific class of eukaryotic small RNA.

mRNA Messenger RNA – transcript of open reading frame.

NABP Nucleic acid binding protein.

ORF Open reading frame – protein-coding DNA fragment.

pAgo Prokaryotic argonaute – bacterial/archaeal homolog of the eukaryotic key protein of RNA interference.

piRNA Piwi-interacting RNA – specific class of eukaryotic small RNA.

Piwi P-element-induced wimpy testis – subclass of the eukaryotic Argonaute protein.

RAMP Repeat associated mysterious protein – subclass of Cas proteins.

RNAi RNA interference – RNA-dependent pathway that leads to silencing and/or degradation of RNA targets.

RNAP RNA polymerase – protein complex responsible for transcription.

SAM S-adenosyl methionine – metabolite involved in methyl group transfer.

SD Shine Dalgarno sequence – ribosome binding site of mRNA.

siRNA Small interfering RNA – specific class of eukaryotic small RNA.

sRNA Small RNA.

tRNA Transfer RNA – RNA molecule involved in translating a messenger RNA into a protein.

Trp Tryptophan – amino acid.

UTR Untranslated region – part of mRNA transcript that is not translated.

Introduction

Like all living cells, bacteria rely on a myriad of metabolic pathways for the generation of energy and biomass to support maintenance and growth. Bacteria that thrive in ecosystems with fluctuating physical and chemical conditions have evolved control mechanisms that allow them to efficiently adjust their metabolic infrastructure by switching on appropriate biochemical pathways, while switching off others. The regulatory mechanisms responsible for fine-tuning these pathways are of major importance for optimal fitness. Control can be executed at all possible levels: DNA transcription, messenger RNA (mRNA) translation, enzyme activity, protein–protein interactions, or protein localization. Often, regulation acts on more than one level of a pathway. A classical example is the regulation of the tryptophan (Trp) biosynthesis pathway (see [Box 1](#)).

Although the analysis of regulation of cellular processes has often focused on control by proteins, it has become clear during the last decades that small RNA (sRNA) molecules also exert many regulatory functions. During the 30 years since the first discovery that bacterial sRNA molecules regulate plasmid replication, the insight into sRNA pathways has increased exponentially.

Most sRNAs act at the level of transcription and translation of mRNA. These sRNAs can be divided into (1) *cis*-encoded RNA elements that are either part of the transcript they target (riboswitches, usually encoded in the 5′ untranslated region of transcript (UTR)), or derived from the opposite strand (antisense sRNA, with perfect complementarity to the target mRNA) and (2) *trans*-encoded sRNAs that are encoded by distinct genomic loci, acting on mRNA through direct base pairing with imperfect complementarity. *cis*-Acting riboswitches

undergo a conformational change upon temperature increase or substrate binding that affects transcription/translation of the downstream open reading frame (ORF). Both *cis*- and *trans*-encoded antisense sRNAs modulate either mRNA transcription, translation, or mRNA stability. Many sRNAs of these classes mediate downregulation of gene expression, but some can also activate genes.

Other classes of sRNAs specifically bind to proteins (enzymes) and as such affect their functionality (activity). In addition, new classes of sRNAs have recently been discovered that make use of dedicated protein components for exerting their specialized functions. For example, sRNAs derived from

Box 1

To avoid unnecessary energy consumption, activation of the tryptophan (Trp) biosynthesis pathway only occurs when intracellular tryptophan levels are low. Several regulatory mechanisms controlling this pathway have been described. (1) In *Escherichia coli*, tryptophan activates a repressor (TrpR) that negatively regulates expression of the *trp* operon (negative feedback regulation). (2) In *Pseudomonas aeruginosa*, indoleglycerol phosphate, a Trp biosynthetic pathway intermediate, induces TrpI, an activator of transcription of tryptophan biosynthesis genes. Indoleglycerol phosphate levels increase during Trp biosynthesis, giving rise to positive feedback. (3) When tryptophan levels are low, uncharged tRNA^{Trp} accumulate. In *E. coli*, the presence of tandem tryptophan codons in the leader peptide of the *trp* operon causes stalling of ribosomes when uncharged tRNA^{Trp} are relatively abundant. This attenuation permits the formation of an anti-terminator loop, instead of the terminator loop that is present otherwise, thereby allowing for transcription (and translation) of the remainder of the operon to proceed. (4) In *E. coli*, the end product of the pathway (Trp) inhibits the activity of the first enzyme in the biosynthetic pathway (anthranilate synthase), giving rise to negative feedback regulation.

clustered regularly interspaced short palindromic repeat (CRISPR) loci protect the cell against invading viral and plasmid DNA. Although the eukaryotic RNA interference (RNAi) system functions in defense as well, the protein components involved in CRISPR-based defense differ substantially from their eukaryotic counterparts. The core enzyme Argonaute is the only protein component of the RNAi pathway that is conserved in prokaryotes. It has recently been hypothesized that prokaryotic Argonaute (pAgo) is also involved in sRNA (or DNA)-mediated antiviral defense. Altogether, prokaryotic sRNA molecules are involved in a wide range of regulatory processes that will be outlined in more detail below.

cis-Acting sRNAs – Riboswitches

A relatively simple means of regulating gene expression relies on the formation of secondary structures within the mRNA through internal base pairing. These secondary structures may be influenced (switched on/off) by physical or chemical signals as described below, and either interfere with transcription/translation of the mRNA itself or affect the stability of the transcript. Often the secondary structure occludes the Shine–Dalgarno (SD) sequence, hence interfering with ribosome binding and translation initiation.

RNA Thermosensors

In the case of RNA thermosensors, the SD masking structure is usually a regular hairpin that is stable only at lower

temperatures. At elevated temperatures, the helical structure melts, making the SD sequence accessible for ribosome binding and translation initiation (**Figure 1(a)**). This type of regulation often controls genes that are involved in response to sudden temperature increase, such as heat-shock genes, and virulence gene expression after entry in a warm-blooded (mammalian) host. The σ_{32} (RpoH) containing RNA polymerase (RNAP) holoenzyme plays an important role in the *Escherichia coli* heat-shock response. Translation of the *rpoH* mRNA is regulated by a well-studied thermosensor that only allows efficient translation at elevated temperatures. This thermosensor contains four hairpin structures that encompass the entire SD sequence as well as the start codon. The imperfect complementarity in the stems causes enough destabilization for immediate melting of the structure at slightly elevated temperatures, while favoring the hairpin structure at lower temperatures. Introducing stabilizing point mutations in the σ_{32} thermosensor sequence strongly decreases translation rates of the mRNA during heat shock, because it has become unresponsive to temperature change.

Other well-studied examples of thermosensors include the 5'-UTR of the phage λ cIII gene that is involved in deciding whether the lytic or lysogenic pathway of the viral lifecycle will be entered. Another example is the repression of heat-shock gene expression (ROSE) element that is found upstream of several *Bradyrhizobium japonicum* genes. Analogous elements probably exist in other organisms as well. Like the *rpoH* thermosensors, these structures comprise a set of stem-loop structures that include the SD sequence and the AUG start codon. In addition, a certain number of mismatches are required for melting in response to a small increase in temperature.

Figure 1 Riboswitches are *cis*-acting regulatory elements that are usually located in the 5' UTR of the mRNA they regulate. Upon elevated temperature (temperature-dependent riboswitch) or ligand binding (ligand-dependent riboswitch), their conformation changes, resulting in alterations in mRNA transcription or translation. Riboswitches serve as an on/off switch, and ligand binding/elevated temperature can either cause inhibition (off-state) or relieve inhibition of mRNA transcription/translation (on-state). In the off-state, either the SD sequence is masked (interference with translation), or a transcriptional terminator stem-loop is formed (interference with transcription). In the examples depicted here, temperature-dependent and ligand-dependent riboswitches that control translation by masking the SD sequence are shown. The secondary structure of a temperature-dependent riboswitch is very sensitive to small increases in temperature, due to the mismatches present in the stem-loop. The melting of the secondary structure allows translation (or transcription when the stem-loop is a transcription terminator) of the downstream gene, since the SD sequence is no longer masked. Ligand-dependent riboswitches contain an aptamer region that specifically binds a ligand, which leads to structural rearrangements in both the aptamer region, as well as the downstream gene expression region. In this example, the structural rearrangements lead to masking of the SD, but ligand-dependent riboswitches are known where the structural rearrangements lead to exposure of the SD sequence, or where transcriptional terminators are formed or lost.

RNA Ligand Sensors

The majority of the riboswitches requires the binding of a ligand, rather than elevated temperature, to induce structural rearrangements. The high number of ligand-dependent riboswitches that have been identified illustrates their importance. These riboswitches consist of a ligand-binding domain and a gene expression domain. The ligand-binding domain, also known as the 'aptamer region' (50 up to several hundreds of nucleotides (nt) in size), functions as a highly specific receptor for metabolites present in the cell. Binding of the metabolite causes formation of alternative secondary structures encompassing the aptamer region and part of the downstream sequence. Generally, structural rearrangements upon ligand binding result in interference with translation (masking of the SD sequence) of the transcript (Figure 1(b)) or with transcription (e.g., formation of a hairpin structure (terminator) that aborts further transcription by RNAP). However, some examples of riboswitches that promote gene expression upon metabolite binding are also known. In these cases, the structural rearrangements lead to the exposure of the SD sequence or the formation of anti-terminator structures (alternative secondary structures that prohibit the formation of the transcription terminator).

A riboswitch makes the mRNA responsive to the availability of nutrients or metabolites inside the cell. This type of regulation is often found in mRNAs that encode proteins involved in the uptake or biosynthesis of the metabolite that it binds. The ligands for a riboswitch can be as simple as a metal ion, or as complex as amino acids and complex cofactors. In some cases, several genes are controlled by the same 5' riboswitch. For example, the S-adenosyl methionine (SAM) riboswitch, which recognizes SAM (important for methylation reactions), is found upstream of a number of *Bacillus subtilis* genes that are involved in methionine and SAM biosynthesis and uptake. When the SAM riboswitch is in the ligand-bound state, expression of the downstream genes is switched off. The structural rearrangements that take place after ligand binding involve both the aptamer and the downstream gene expression domain (Figure 1(b)). As a result, the responsiveness of the riboswitch-containing transcript to the ligand depends not only on the affinity of the aptamer to the ligand but also on the downstream gene expression domain. Although the aptamers in all SAM riboswitches are identical and, thus, have equal affinities for SAM, translation of different genes is not equally responsive to SAM due to differences in the downstream gene expression domain. The mRNAs of the anabolic pathway components are highly sensitive to SAM, so that they are not translated until SAM levels become almost depleted. By contrast, the mRNAs of the components involved in SAM uptake are much less sensitive to SAM, and repression of these genes is relieved while relatively high levels of SAM are still present. This additional layer of regulation causes that SAM uptake systems are switched on first when SAM levels drop. If this has no effect, SAM levels further drop to a level that relieves repression on the mRNA for SAM biosynthesis genes.

A decreased sensitivity can also be accomplished by multiple copies of the same riboswitch, since ligand binding to each aptamer is needed. An example of this is the riboswitch that

binds uncharged transfer RNA (tRNA)^{Thr} to control the *thrZ* gene (threonyl-tRNA synthetase) in *B. subtilis*. Some mRNAs also contain several different 5' riboswitches to allow integration of multiple signals. For example, the mRNA of *metE* (encoding vitamin B₁₂-independent methionine synthase) contains two riboswitches, one of which binds SAM, which is the end product of MetE (feedback control), and the other vitamin B₁₂. The presence of vitamin B₁₂ signifies that a more efficient pathway for SAM biosynthesis can be utilized, which makes use of the vitamin B₁₂-dependent methionine synthase encoded by *metH*.

The generation of transcripts containing a riboswitch that blocks translation may seem a waste of resources compared to regulation at the level of transcription. However, it enables a more rapid response to temperature shock or changes in metabolite levels, which may be worth the expense. To avoid further spoilage of resources due to partial translation of the sequence, the riboswitch is almost always located at the 5'-UTR of the transcript.

cis-Encoded sRNAs – Antisense

Apart from elements in the mRNA itself that regulate transcription or translation through secondary structure formation, gene expression can also be regulated by small antisense RNA molecules that act through base pairing with the target mRNA (Figure 2(a)). The complementarity between the target mRNA and the sRNA is perfect in the case of *cis*-encoded sRNAs, because they are transcribed from the opposite strand of the same locus as the target mRNA. In most cases, *cis*-encoded sRNAs inhibit transcription or translation of their target transcript. Some function as anti-toxin by repressing the translation of a toxic protein. These toxin/anti-toxin systems are often encoded on large conjugative plasmids and ensure that the plasmid is retained in the cell and its progeny, because loss of the short-living anti-toxin causes cell death due to the long-living toxin. These toxin/anti-toxin pairs are sometimes found on the chromosome of bacterial species as well, where they carry out functions that are not yet well understood, possibly being beneficial for the host by inducing slow growth under stress conditions, or providing defense against plasmids with the same toxin/anti-toxin system.

Other *cis*-encoded sRNAs bind polycistronic mRNA transcripts to modulate expression levels of individual genes within the operon. An example of this type of regulation is the base pairing of the antisense sRNA GadY with the *gadXW* mRNA, encoding GadX and GadW, which respectively activate and repress the glutamate-dependent acid response in *E. coli*. The base pairing between GadY and *gadXW* mRNA leads to cleavage between the *gadX* and *gadW* coding sequences and increased *gadX* transcript levels. Other examples are the antisense sRNA-induced transcription termination after *fata* in the *fatDCBAangRT* operon in *Vibrio anguillarum*, and sRNA-induced cleavage between the *isiA* and *isiB* coding sequences in the *isiAB* transcript in *Synechocystis*.

trans-Encoded sRNAs

Similar to *cis*-encoded sRNAs, *trans*-encoded sRNAs regulate mRNA translation and stability. They differ from *cis*-encoded

Figure 2 Small noncoding RNA molecules can regulate mRNA stability or translation (antisense RNA), or protein functionality (sequestration). Antisense sRNAs can be either *cis*-encoded or *trans*-encoded. (a) The complementarity between the target mRNA and the sRNA is perfect in the case of *cis*-encoded sRNAs, since they are transcribed from the opposite strand of the same locus as the target mRNA. The outcome of base pairing between the target mRNA and *cis*-encoded sRNA is usually inhibition of translation or degradation of the mRNA, or modulation of the expression of genes in an operon, resulting from sRNA-induced cleavage between ORFs in a polycistronic transcript. (b) *Trans*-encoded sRNAs show only limited complementarity with their target and need the hexameric Hfq to exert their regulatory function. Hfq facilitates binding of *trans*-encoded sRNA to target mRNA. Binding of the sRNA to the target mRNA sequence usually occurs at the 5' end to mask the SD sequence and/or start codon of the mRNA. Although *trans*-encoded sRNAs usually inhibit translation or cause degradation of the mRNA, examples that cause enhanced translation of the mRNA transcript have been described as well. In these cases, the *trans*-encoded sRNAs bind a stem-loop that functions as a transcription terminator (anti-termination), or base pairing induces structural rearrangements in the mRNA that result in exposure of the SD sequence. (c) Some sRNAs are known that modulate the functionality of a nucleic acid-binding protein (NABP). These sRNA molecules function by sequestering the NABP, due to the presence of a motif or structure to which the NABP binds with high affinity.

sRNA in that they are derived from loci other than their targets. Consequently, the base pairing region between the sRNA and the target mRNA contains only partial complementarity. In most cases, the sRNA binds the mRNA sequence at its 5' end to mask the SD sequence and/or start codon (Figure 2(b)). However, *trans*-encoded sRNAs that enhance translation or transcription of the mRNA transcript through an anti-antisense mechanism have been described as well. In this case, base pairing of the sRNA leads to structural rearrangements in the mRNA that result in exposure of the SD sequence or in anti-termination. The best-studied example is the regulation of RpoS, an alternative σ -factor, by the sRNAs DsrA and RprA in *E. coli*. These two sRNAs activate RpoS translation through base pairing with an inhibitory stem of a hairpin present at the 5' end of the RpoS transcript. The genes that are transcribed in an RpoS-dependent manner are important for entry in the stationary phase. The sRNA RprA is transcribed in response to envelope stress, whereas DsrA is transcribed especially at low temperatures.

A key player in regulation by *trans*-encoded sRNA is the protein Hfq, which functions as an RNA chaperone. The hexameric Hfq binds and protects sRNA and is required for the formation of low-complementarity duplexes between the *trans*-encoded sRNA and the target mRNA. In *E. coli* *hfq* mutant strains *trans*-encoded sRNAs fail to exert their regulatory effect. Hfq is probably also involved in melting secondary structures of the target mRNA, or serves as a platform for the sRNA-mRNA interaction only.

A single *trans*-encoded sRNA can have multiple targets, because full complementarity is not required. In some cases

a single sRNA targets multiple genes involved in the same pathway. For example, in *E. coli* the sRNA RyhB is transcribed in response to iron limitation. RyhB targets the mRNA of different operons encoding iron-binding proteins, including *bfr* (bacterioferritin), *sdh* (succinate dehydrogenase), and *sodB* (superoxide dismutase). The Hfq-dependent base pairing between these mRNAs and RyhB leads to RNaseE-dependent degradation of both the mRNA and RyhB. By downregulating the levels of these iron-binding proteins, the availability of iron for essential cellular processes increases.

sRNAs That Bind Protein to Modulate Their Activity

Few examples are known of sRNAs that bind proteins to modulate their activity. These sRNA molecules contain a motif or structure that causes high affinity binding by a specific nucleic acid-binding protein, leading to sequestration of the latter (Figure 2(c)). For example, the σ^{70} -containing RNAP has high affinity for the 6S sRNA due to its conserved secondary structure that is highly reminiscent of the DNA conformation in an open promoter. During exponential growth, the majority of transcription is carried out by RNAP containing σ^{70} . However, when cells enter the stationary phase upon nutrient depletion, alternative sigma factors associate with the core RNAP leading to transcription switching. The 6S sRNA facilitates transcription by alternative sigma factors, since the high affinity binding of σ^{70} to 6S leads to sequestration of the former. As a result, transcription from certain σ^{70} promoters

is inhibited, and instead, transcription mainly takes place from σ^S promoters.

In *E. coli* two sRNAs, CsrB and CsrC, regulate CsrA protein activity in an analogous manner. Dimers of CsrA act as global posttranscriptional regulators of carbon metabolism. These dimers exert their regulatory function by binding target mRNA sequences with GGA motifs in their 5'-UTR. As CsrB and CsrC, each contain multiple GGA motifs, an increase in their levels leads to sequestration of CsrA.

CRISPR-Based Defense against Infection

A more recently discovered class of prokaryotic sRNA molecules is involved in defense against invaders, such as viruses and conjugative plasmids. The hallmark of this defense system are loci of CRISPR with often adjacently located CRISPR-associated (*cas*) genes. CRISPR loci are present in ~40% and ~90% of the sequenced bacterial and archaeal genomes, respectively, and consist of repeating sequences of typically 30 nt that are separated by invader-derived sequences of similar length, called spacers. The presence of a spacer provides specific immunity against infective elements with a complementary sequence. The size of one CRISPR locus ranges from a few to hundreds of spacer/repeat units. CRISPR loci evolve rapidly in natural ecosystems through frequent spacer acquisition (known as 'CRISPR adaptation') and spacer loss. In fact, a CRISPR array can be seen as a record of recent infections that a lineage has overcome.

The CRISPR-based immune response requires transcription of the CRISPR locus into a long pre-crRNA molecule, and subsequent maturation to yield small crRNAs that serve to guide the defense. The protein machinery needed for maturation of the crRNA transcript and for subsequent CRISPR interference is encoded by the *cas* genes. Over 45 families of *cas* genes exist, that are found in nine typical combinations, known as 'subtypes'. Each subtype is named after a representative organism (e.g., *E. coli* K12 has subtype E). A single subtype contains between four to 20 *cas* genes that suffice for an anti-invader response. All CRISPR harboring species contain the core genes *cas1* and *cas2*, and usually a number of sub-type specific *cas* genes. Despite the variation in *cas* gene content between the subtypes, the mechanistic processes that underlie CRISPR-based defense appear to be variations on a theme.

The mechanism of CRISPR-based defense can be divided in three stages: (1) CRISPR adaptation, (2) CRISPR expression, and (3) CRISPR interference (Figure 3(a)). CRISPR adaptation takes place upon phage encounter and results in one or more new spacers being added to the existing CRISPR array. So far, CRISPR adaptation has only been studied in *Streptococcus thermophilus*, a lactic acid bacterium important in the dairy industry. This bacterium contains only four *cas* genes (*csn1*, *csn2*, *cas1*, and *cas2*). Inactivation of the species-specific *csn2* gene results in an inability to integrate new spacers, while gene disruption of *csn1* abolishes CRISPR interference, regardless of the presence of a virus-derived spacer sequence.

In the second stage, CRISPR expression, the array is transcribed into a long pre-crRNA molecule. In *E. coli* K12, eight *cas* genes are present, of which five (*casA*, *casB*, *casC*, *casD*, and

casE) encode proteins that form a multimeric protein complex named 'CRISPR associated complex for antiviral defense' (Cascade). CasE is a metal-independent endoribonuclease needed for the maturation of pre-crRNA. Cleavage by CasE within each repeat sequence generates mature crRNA molecules with the length of a single spacer and a single repeat. A single mature crRNA remains bound by the Cascade complex, forming a ribonucleoprotein complex. In *Pyrococcus furiosus*, maturation of the pre-crRNA is carried out by Cas6. In this species, the crRNAs are further trimmed at their 3' end. Comparison of the crystal structures of CasE from *Thermus thermophilus* and Cas6 from *P. furiosus* reveals that these proteins have a similar architecture. CasE has a catalytic histidine residue, whereas a catalytic triad (His, Tyr, Lys) has been proposed for Cas6. The mature crRNAs in *P. furiosus* are transferred to a Cas protein complex that is composed of six proteins of the so-called repeat-associated mysterious protein (RAMP) family, forming a ribonucleoprotein complex.

During the third stage of CRISPR-based defense, CRISPR interference, the target nucleic acids are recognized and inactivated. Evidence is accumulating that several CRISPR/Cas systems target viral and plasmid DNA. In *E. coli* and in *S. thermophilus*, the presence of virus-derived spacer sequences confers immunity and the complementary target sequence can be located either on the coding or on the template strand, which points towards DNA as the potential target. In *Staphylococcus epidermidis*, the targeting of a noncoding sequence on a plasmid confers immunity, whereas introducing a self-splicing intron in the protospacer, leading to a complementary sequence in the mRNA but not in the DNA, does not provide protection. Although target DNA degradation has not been observed yet, these convincing lines of evidence point toward DNA as the prime target in these CRISPR/Cas subtypes. In addition to the crRNA-loaded Cascade complex from *E. coli*, the predicted nuclease/helicase Cas3 is required for resistance against phage infection, possibly to carry out target DNA cleavage.

Although the aforementioned findings suggested that all CRISPR/Cas systems target DNA directly, a whole new variation on the CRISPR interference theme came from studies done on a system from *P. furiosus*. *In vitro* the RAMP containing Cas protein complex loaded with trimmed crRNA is capable of cleaving complementary single-stranded RNA. The observed cleavage takes place at a well-defined position, 14 nt from the 3' end of the crRNA. This sRNA-guided RNA degradation is mechanistically similar to RNAi-based defense against virus infections in plants, although no evolutionary relation exists between the proteins of CRISPR/Cas and RNAi (see below).

Prokaryotic Argonaute

In RNAi in eukaryotes, three major forms of small regulatory RNAs can be distinguished: microRNAs (miRNAs), small interfering RNAs (siRNAs), and piwi-interacting RNAs (piRNAs). miRNAs are endogenously encoded noncoding RNAs that regulate cellular processes through sequence-specific transcriptional or posttranscriptional gene silencing. Initially, it was thought that siRNAs are exclusively derived from extrachromosomal elements such as viruses, and sequence-specifically

Figure 3 The *Escherichia coli* K12 CRISPR/*cas* locus consists of eight *cas* genes, which encode the machinery to carry out each of the three stages of the CRISPR immune response. Upon phage infection, Cas1 and/or Cas2 may mediate the integration of new spacer sequences in the existing CRISPR array. During the subsequent expression stage, the Cascade protein complex is formed and the CRISPR locus is transcribed into a long pre-crRNA molecule. Cascade mediates the maturation of the pre-crRNA transcript by cleavage within the repeat sequence, at the base of each stem-loop. The mature crRNA remains bound to Cascade, and the crRNA-loaded Cascade specifically binds the double-stranded viral DNA during the CRISPR interference stage. In concert with Cas3, the elimination of the virus is accomplished, probably through cleavage of the viral DNA.

suppress these elements. However, the recent discovery of endogenously encoded siRNAs has made the boundaries between miRNAs and siRNAs less well defined. The biogenesis and function of miRNAs and siRNAs are discussed elsewhere in this encyclopedia. Despite their distinct roles and origins, miRNAs and siRNAs share common themes in their mechanistic pathways. Two core proteins involved in both RNAi pathways are Dicer and Argonaute (note that it can be distinct paralogous proteins in one organism that are involved in either pathway). Dicer contains two RNaseIII domains that each cleave one strand of a double-stranded RNA (dsRNA) precursor molecule, generating short dsRNA. One of these strands (the guide) is then transferred to Argonaute, which facilitates base pairing with complementary RNA target sequences. miRNAs generally display imperfect base pairing while siRNAs generally display perfect base pairing with the target transcript.

The P-element-induced wimpy testis (PIWI)-domain of Argonaute, which shares structural homology to RNaseH family proteins, can cleave the complementary target RNA in case of perfect base pairing. Subsequent recycling of the sRNA-protein complex enhances the silencing effect.

Argonaute is the only protein component of RNAi of which homologs can be found in prokaryotes. Prokaryotic *argonaute* genes have been identified in ~80 sequenced genomes. Interestingly, crystal structures and *in vitro* activity assays of these prokaryotic Argonaute proteins provided the RNAi field with a lot of insight in the mechanism of target binding and cleavage. However, their role in prokaryotes remains elusive. It has recently been hypothesized that they are involved in antiviral (and anti-plasmid) defense, which is supported by several observations: (1) in eukaryotes many homologous Argonaute proteins are involved in

antiviral defense, (2) phylogenetic analysis of prokaryotic *argonaute* gene sequences suggests extensive horizontal gene transfer (HGT), which is typically observed for virus defense systems, (3) comparative gene neighborhood analysis revealed enriched association of *argonaute* genes with known phage-defense genes such as restriction endonucleases, (4) in virus-infected *T. thermophilus* cultures, the expression of the *ago* gene, as well as the *cas* genes is enhanced, and (5) Argonaute proteins from *Aquifex aeolicus* and *T. thermophilus* display DNA- and RNA-guided nuclease activity *in vitro*.

Despite its putative role in antiviral defense, the exact mechanism of virus defense remains to be elucidated. Small guide RNAs could direct base pairing and target cleavage analogously to RNAi in eukaryotes. However, prokaryotic Argonaute shows a higher affinity for guide-DNA than for guide-RNA and contains both DNA- and RNA-guided nuclease activity. Despite *in vitro* RNA degradation, the association of Argonaute with putative dsDNA nucleases suggests that DNA is being targeted directly. More insight in this antiviral defense system, which is supposed to be based on small nucleic acids, is to be expected in the near future.

Conclusions

Altogether sRNA molecules have diverse functions in prokaryotes (both bacteria and archaea), ranging from regulation of gene expression, mRNA translation, and protein functionality, to guiding target recognition in the recently discovered CRISPR-based defense system. The presence of Argonaute homologs in prokaryotes suggests the existence of additional host defense pathways utilizing small nucleic acids.

C2 domains Domains of proteins involved in plasma membrane targeting. They consist of a β -sandwich motif composed of eight β -strands that coordinates two or three calcium ions.

Cysteine accessibility mutagenesis A technique in which single residues are mutated to cysteine and reactivity to

membrane impermeable sulfhydryl reacting agents is determined.

FLAG antibody An antibody to an epitope with the amino acid sequence DYKDDDDK.

Nuclear magnetic resonance (NMR) and X-ray crystallography Methods for determining the arrangement of atoms in proteins.

Introduction

Ca^{2+} is one of the most abundant metals in living organisms, and Ca^{2+} movements across cell membranes play a central role in cell signaling. Among the plasma membrane proteins transporting Ca^{2+} across the membrane is the Na^{+} – Ca^{2+} exchanger (NCX), which utilizes the electrochemical gradient of Na^{+} to extrude Ca^{2+} from the cell. During each reaction cycle, one Ca^{2+} is moved out of the cell while three Na^{+} are transported into the cytoplasm. This is considered the normal mode of NCX (or forward mode). However, under appropriate Na^{+} and Ca^{2+} gradients NCX can catalyze Ca^{2+} influx (reverse mode).

NCX is a ubiquitous protein found in tissues such as kidney, smooth muscle, and brain. However, NCX is most abundant in the heart where its fundamental role in contractile events has been extensively investigated. A milestone in the studies of NCX was its cloning in 1990 which, in conjunction with the development of the giant patch technique by Hilgemann, has allowed a detailed analysis of both its biophysical properties and physiological function.

The emphasis of this article is on recent developments regarding the structure/function relationships of the cardiac exchanger (NCX1). Excellent books and reviews covering the topics not discussed here are available to the reader interested in learning more about NCX.

The NCX1 Membrane Topology

The topology of NCX1 has been extensively investigated using a combination of cysteine accessibility mutagenesis, epitope mapping, and functional analysis of mutants. NCX1 is composed of nine transmembrane segments (TMSs) with a large, cytoplasmic loop between TMS 5 and 6. Also, a pair of reentrant loops in the regions known as the α -repeats has been proposed. Much of this information comes from cysteine accessibility mutagenesis in which cysteines are introduced at various locations in NCX1. The addition of membrane impermeant sulfhydryl-modifying reagents to the extracellular or intracellular surface then makes it possible to determine on which side of the membrane the cysteine resides. Figure 1 is a cartoon representation of NCX1 with residues that have been mutated to cysteine.

Residues highlighted in red are sensitive to extracellular sulfhydryl modification while residues highlighted in blue are sensitive to intracellular modification. One residue, at position 842, is accessible from either side of the membrane. Epitope mapping experiments have been conducted by first obtaining antibodies that bind to a known region of NCX1 then examining whether the antibody binds at the intracellular or extracellular surface of NCX. In a first report, monoclonal antibodies were raised to the full length NCX1 then mapped to the large hydrophilic loop of NCX1 by screening an expression library composed of fragments of NCX1. A second approach was to generate antibodies against small peptide fragments of NCX1 and a third approach was to introduce the epitope to the FLAG antibody at known sites of NCX1. The locations of the epitopes were mapped to the extracellular surface by direct antibody binding to cells expressing NCX1 or to the intracellular surface if the antibody was only able to bind the cells after permeabilization. In Figure 1, the approximate center of each epitope is circled in blue. Both the cysteine accessibility and epitope mapping techniques support the model for NCX1 shown in Figure 1. In this model, NCX1 is composed of nine α -helical TMS of 17–24 residues in length with a large cytoplasmic loop between TMS 5 and 6 and reentrant loops between TMS 2 and 3 and between 7 and 8. At least one residue in each of the loops connecting TMSs has been mapped to an intracellular or extracellular surface. The sole observation that does not support the model is for epitope mapping at position 37. In that experiment, a FLAG epitope inserted at residue 37 of NCX1 was only accessible after permeabilizing the cell with the detergent Triton X-100. Given other data that show the amino terminus of NCX1 is extracellular, it seems most likely that residue 37 is extracellular but with limited accessibility in the absence of detergent.

NCX1 Helix Packing

In a series of studies, the packing arrangement of TMSs has been examined by sulfhydryl cross-linking. By introducing pairs of cysteines into a cysteine-free NCX1, treating with sulfhydryl cross-linking reagents, and examining mobility shifts on sodium dodecyl sulfate–polyacrylamide gel electrophoresis (SDS–PAGE), it is possible to determine which TMSs are near

Figure 1 Membrane topology of NCX. Shown are NCX residues and their secondary organization. This model is based on cysteine accessibility and epitope mapping studies. Residue numbers within the red filled circles are accessible to extracellular sulfhydryl reagents while positions indicated by blue filled circles are affected by intracellular application of sulfhydryl reagents. The open blue circles indicate locations of epitopes of NCX. The crystal structures of the exchanger Ca^{2+} -binding domains (CBD1 and CBD2) are also presented. They are shown with an arbitrary orientation since the structure of the arrangement of the two CBDs has not been resolved yet. In the case of CBD2, the Ca^{2+} -free (yellow) and Ca^{2+} -bound (blue) forms are shown. Ca^{2+} ions are indicated in green (CBD1) and blue (CBD2). Reproduced from Nicoll DA, Sawaya M R, Kwon S, et al. (2006) The crystal structure of the primary Ca^{2+} sensor of the $\text{Na}^+/\text{Ca}^{2+}$ exchanger reveals a novel Ca^{2+} binding motif. *Journal of Biological Chemistry* 281(31): 21577–21581 and Besserer GM, Ottolia M, Nicoll DA, et al. (2007) The second Ca^{2+} -binding domain of the $\text{Na}^+-\text{Ca}^{2+}$ exchanger is essential for regulation: Crystal structures and mutational analysis. *Proceedings of the National Academy of Sciences of the United States of America* 104(47): 18467–18472.

one another in the folded protein. Extensive cross-links between the two halves of NCX1 have been observed and a model for helix packing, calculated as the smallest sum of the length of cross-links, is shown in Figure 2(a).

In this model, with the exception of TMS 6, the two halves of NCX are segregated. TMS 2, 3, and 7, which comprise portions of the α -repeats, regions of sequence similarity that are likely the result of a gene duplication event, are opposite one another. Also functionally important residues (e.g., Glu¹¹³, Ala¹⁴⁰, and Asp⁸¹⁴) are directed inward, away from the lipid bilayer (not shown).

NCX1 Dimerization

The first evidence that NCX1 may not exist solely as a monomer came from studies where cyan fluorescent protein (CFP)- and yellow fluorescent protein (YFP)-tagged NCX1 proteins were coexpressed and Ca^{2+} -sensitive interactions between the fluorescent CFP and YFP tags could be observed. Subsequently, we detected cross-linking between certain single cysteine-containing NCX proteins. Thus, NCX can exist as a dimer or

perhaps as a higher-level multimer in the membrane. Neither of these studies was able to determine the biophysical or physiological implications of NCX1 multimers.

Function of NCX Transmembrane Domains

There has been considerable study on the effects of mutations in the TMSs of NCX, especially those TMSs that form the α -repeat segments, TMSs 2, 3, and 7, as well as the putative reentrant loops. In one study, mutations to several residues in each of the putative reentrant loops of the α -repeats altered the affinity of NCX for extracellular, transported Ca^{2+} . In another study, some of the same mutations in the putative α 1-repeat reentrant loop were examined with respect to intracellular ions and found to have altered affinities for intracellular Na^+ but not intracellular Ca^{2+} . Additional mutations in TMS2 and TMS3 cause altered affinity for intracellular Na^+ affinity and/or selectivity but little or no effect on intracellular Ca^{2+} affinity. Particularly, replacement of residues A140 and I147 within TMS3 drastically decreased the sensitivity of NCX for transported Na^+ (see Figures 2(b)–2(d)), indicating an important

Figure 2 NCX helix packing. Panel (a) shows a top view of the packing arrangements of the NCX transmembrane segments (TMSs). This model is based on extensive crosslinking studies showing proximity of TMSs. Pairs of cysteine were introduced into a cysteineless exchanger and intramolecular cross-linking was detected as changes in electrophoretic mobility. In this model, TMS 2, 3, and 7, which encompass portions of the α -repeats, are opposite to each other. These regions are important for transport of Na^+ and Ca^{2+} ion, as mutagenesis studies reveal. Panel (b) shows that residues Ala¹⁴⁰ and Ile¹⁴⁷ of TMS3 face the same side of the α helix. Replacement of either of these two residues significantly alters the transport properties of NCX. Panel (c) illustrates outward currents recorded in the presence of the indicated Na^+ concentrations for WT and I147S exchangers, while the corresponding Na^+ -dependency curve is shown in panel (d). The normalized current vs. Na^+ concentration for mutant A140C is also presented.

role of these residues in ion transport. Mutations of several hydrophilic residues in TMSs 2, 3, 5, 6, and 7 result in inactive NCXs. TMS5 is especially interesting because the mutated residues correspond to a region with sequence similarity to the Na^+/K^+ adenosine triphosphatase (ATPase).

Structure–Function of NCX Cytoplasmic Domains

Cytoplasmic Loop f

NCX is comprised of 938 amino acids, ~550 of which make a large cytoplasmic loop (loop f) located between transmembrane segments 5 and 6 (see Figure 1). This portion of the exchanger is not required for transport (a mutant lacking most of this loop, $\Delta 240$ –679, still retains exchange activity) but it plays an important role in regulation being the target of factors such as cytosolic Na^+ and Ca^{2+} , phosphatidylinositol 4,5-bisphosphate (PIP_2), anionic lipids, and protons. Insights into the structure of this portion of the exchanger are required to unveil its regulatory properties. Here are summarized the latest findings.

The Exchanger Inhibitory Peptide Region and Na^+ -Dependent Inactivation

At the N-terminus of this loop is found the exchanger inhibitory peptide (XIP) region. This is a stretch of hydrophobic and positive residues (residues 218–239) named after a synthetic

peptide (XIP) with identical sequence which potently inhibits exchanger activity. The endogenous XIP region is involved in several regulatory processes such as Na^+ -dependent inactivation (see Figure 3).

This process describes a slow decay of exchanger current due to the presence of high intracellular Na^+ concentrations. It is thought that the binding of cytosolic Na^+ to transport sites drives the exchanger into a nonfunctional state, without involving alternative Na^+ -binding domains. However, the large cytoplasmic loop is involved in this regulation since electrophysiological data show that replacement of strategic residues within the XIP region alters both the rate and extent of inactivation. This is shown in Figure 3(a).

In addition to being involved in the Na^+ -dependent inactivation process, the XIP region is the target for PIP_2 and anionic long-chain fatty acyl CoA esters (acyl CoAs). Anionic lipids stimulate the exchanger activity by counteracting the Na^+ inactivation, as demonstrated in Figure 3(b).

Despite these advances, the molecular details and physiological roles of Na^+ -dependent inactivation are still unclear. Possibly, the XIP region is in contact with the plasma membrane preventing Na^+ -dependent inactivation. Increases in bound Na^+ could destabilize this interaction and trigger inactivation. Both PIP_2 and acyl-CoAs may stabilize the XIP region in a plasma membrane-bound state. This model is speculative. Additionally, since the Na^+ -dependent inactivation occurs primarily at high Na^+ concentrations, its

Figure 3 The XIP region is involved in the Na⁺-dependent inactivation and PIP₂ regulation. Panel (a) shows the amino acid sequence of the XIP region for the WT and mutant exchangers and their corresponding outward currents. Note the decay of the current over time due to the presence of high cytoplasmic Na⁺ (Na⁺-dependent inactivation). The inactivation process is abolished in mutant K229Q and enhanced in mutant F223E. Panel (b) shows the effect of PIP₂ on NCX outward currents recorded using the giant patch technique. Application of 30 μM PIP₂ removed the Na⁺-dependent inactivation in the WT exchanger, and had no or very little effect on mutants F223E and K229Q. From these and other experiments, it was concluded that Na⁺-dependent inactivation is required for PIP₂ effects. (a) Modified from Matsuoka S, Nicoll DA, He Z, and Philipson KD (1997) Regulation of cardiac Na⁺-Ca²⁺ exchanger by the endogenous XIP region. *Journal of General Physiology* 109(2): 273–286. (b) Modified from He Z, Feng S, Tong Q, Hilgemann DW, and Philipson KD (2000) Interaction of PIP(2) with the XIP region of the cardiac Na⁺/Ca²⁺ exchanger. *American Journal of Physiology – Cell Physiology* 278(4): C661–C666.

physiological role is unclear. Cytoplasmic Na⁺ concentrations may not reach the Na⁺ levels necessary to induce inactivation of the exchanger. Likewise, the role of PIP₂ in regulating the Na⁺-Ca²⁺ exchanger *in vivo* is unclear. Further investigations are needed to clarify the function of Na⁺-dependent inactivation and its regulation by lipids.

Linker Domain 1

Residues 239–371, immediately following the XIP region, may be important in transducing the movements of the Ca²⁺-binding domains (CBD1 and CBD2; see below) to the transmembrane segments. Supporting this hypothesis are fluorescence resonance energy transfer (FRET) studies showing large conformation changes within linker domain 1 upon binding of Ca²⁺ to CBD1. Still, no detailed functional studies of this portion of exchanger have been conducted leaving the role of these residues unknown.

The Ca²⁺ Binding Domains

The modulation of exchanger activity by cytoplasmic Ca²⁺ is well documented. Since a first observation about 30 years ago by DiPolo, the field has greatly advanced. Regulatory Ca²⁺ promotes exchanger activation and rescues it from the Na⁺-dependent inactivation. In order to stimulate transport activity, cytoplasmic Ca²⁺ binds to two Ca²⁺-binding domains that are distinct from the Ca²⁺ transport site (see Figure 1). These regions follow linker domain 1 and their structures have been resolved by both nuclear magnetic resonance (NMR) and X-ray crystallography. The first Ca²⁺-binding domain (CBD1) encompasses residues 371–501 and the second CBD2 spans amino acids 501–689. Each CBD is organized into a seven-stranded antiparallel β-sandwich with Ca²⁺ ions bound at the head of the sandwich and an unstructured F–G loop at the opposite end. The principal difference of the two CBDs lies in the heads and F–G loops. CBD1 binds four Ca²⁺, while CBD2 only binds two (Figure 4(a)).

The F–G loops of both CBDs are unstructured, but the F–G loop of CBD2 is a site of alternative splicing. It has been proposed that this alternative splicing results in exchangers with different properties but we have found that removing the F–G loops has no effect on the biophysical properties of NCX1. Thus, it seems more likely that the CBD2 F–G loop is involved in tissue-specific localization or interaction with other proteins. The organization of the conjunct CBDs is at present unknown.

The role of these domains in conferring Ca²⁺ sensitivity to the exchanger has been investigated by mutagenesis and electrophysiology. Replacement of residues coordinating Ca²⁺ at sites 3 and 4 of CBD1 significantly decreases the sensitivity of NCX to regulatory Ca²⁺, while a single-point mutation in CBD2 (E516L) eliminates Ca²⁺ regulation (Figures 4(b) and 4(c)). Still, how the binding of Ca²⁺ is triggered into exchanger activation continues to puzzle investigators. The expectation is that binding of Ca²⁺ to CBD1 and CBD2 results in a change of conformation which translates into NCX activation. Indeed, both biochemical and FRET studies indicate that CBD1 moves in response to Ca²⁺. In contrast, the structure of CBD2 appears similar in both the Ca²⁺-free and -bound forms, although elimination of Ca²⁺ coordination by CBD2 deregulates the exchanger. Additional investigations are required to shed light into the mechanism underlying exchanger regulation. Nevertheless, events describing the underlying exchanger regulation have been postulated. In one hypothesis, a twist in the linker region connecting the two CBDs occurs upon Ca²⁺ binding to CBD1, with a resultant activation of the exchanger.

Figure 4 NCX Ca²⁺ regulation. Panel (a) shows the regions of CBD1 and CBD2 coordinating Ca²⁺. Note that CBD1 coordinates four Ca²⁺ and CBD2 only two. Outward currents recorded from WT NCX and exchangers with mutations in CBD1 (E385A) or CBD2 (E516L) are presented in panel (b). Traces were measured at the indicated cytoplasmic Ca²⁺ concentrations. Increases in cytoplasmic Ca²⁺ activate NCX current and decrease the extent of Na⁺-dependent inactivation. However, activation of mutant E385A required higher Ca²⁺ concentrations than WT. Mutation at position 516 caused the loss of Ca²⁺ regulation. These data underline the importance of both CBD1 and CBD2 in the regulation of NCX by cytoplasmic Ca²⁺. Finally, mutagenesis studies indicate that only Ca²⁺ coordinated by sites 3 and 4 of CBD1 are important for exchanger activation. As shown in panel (c), the affinity of WT and E451A (coordinating mainly Ca²⁺ at site 2 of CBD1) were not significantly different. In contrast, exchanger E385A (affecting coordination of Ca²⁺ at site 3) has decreased NCX affinity for cytoplasmic Ca²⁺. Reproduced from Nicoll DA, Sawaya MR, Kwon S, et al. (2006) The crystal structure of the primary Ca²⁺ sensor of the Na⁺/Ca²⁺ exchanger reveals a novel Ca²⁺ binding motif. *Journal of Biological Chemistry* 281(31): 21577–21581, with permission.

This movement correlates with a change in the electrostatic interaction between the two CBDs. Alternatively (or perhaps concurrently), upon binding of Ca²⁺, CBD2 moves with respect to some other region of the protein or the plasma membrane. This behavior would be similar to what is observed in the structurally similar C2 domains which are recruited to the plasma membrane upon Ca²⁺ coordination. Both theories require experimental validation leaving investigations on the regulation of the exchanger by Ca²⁺ open to new discoveries.

Linker Domain 2

Residues 689–768 link the second CBD to transmembrane segment 6. A portion of linker domain 2 was initially thought to be a transmembrane segment but cysteine scanning mutagenesis studies revealed it to be part of the large cytoplasmic loop. There is no information on the function of this region of the exchanger though insertion of green fluorescent protein (GFP) at this location disrupts the targeting of NCX to the

plasma membrane resulting in retention in the endoplasmic reticulum (unpublished observation). Since the insertion of GFP within the large cytoplasmic loop is well tolerated at other sites, this observation suggests a potential role of these residues in NCX trafficking.

Cytoplasmic Loops b and d

Residues 63–101 and 156–167 constitute cytoplasmic loops b and d, respectively. Few mutagenesis studies have been conducted within these regions of the exchanger and information is limited.

In loop b, replacement of Asn 101 with a Cys abolished the sensitivity of the transporter to regulation by cytoplasmic Ca²⁺ and Na⁺, revealing an important role of this loop in exchanger secondary regulation. Similarly, the histidine at position 165 of loop d is involved in the regulatory effects of Na⁺ and Ca²⁺ as mutations at this site drastically alter regulation. How these two loops exert their regulatory properties is unknown.

Interestingly, these loops flank TMSs 2 and 3 which are involved in ion translocation. Possibly, these cytoplasmic regions represent a structural link between ion translocation and regulation.

The C-Terminus

The C-terminus of NCX1 has also been shown to be intracellular. While no role has yet been assigned to this region, we have found that truncations and most insertions in this region result in nonfunctional exchangers. Thus, the C-terminus is likely important, though a specific role for this part of the exchanger remains to be defined.

Structure–Function of NCX Extracellular Domains

Most of the extracellular loops connecting TMSs are predicted to be short. Although amino acid substitutions are fairly well tolerated, we find that insertions into these regions result in nonfunctional exchangers. One exception is the amino terminus, which is about 40 amino acids long and contains a glycosylation site and a pair of cysteines capable of forming disulfide bonds with the extracellular loop connecting TMSs 6 and 7. The amino terminus can tolerate any number of insertions, deletions, and mutations with no apparent effect on NCX activity.

Glossary

Cortistatins It refers to the short (rat CST-14 and human CST-17) and long (CST-29) biologically active products produced by proteolytic processing of the precursor peptide encoded by the cortistatin gene.

G protein One of a family of related heterotrimeric proteins which binds guanosine triphosphate (GTP) and guanosine diphosphate (GDP). The heterotrimeric forms, which are inactive, become activated at the plasma membrane by agonist-occupied G-protein-coupled receptors (GPCRs) that stimulate the binding of GTP to the G-protein alpha subunit and cause dissociation of the

alpha subunit from the beta-gamma subunit complex. When activated, the G-protein subunits regulate downstream effectors, such as ion channels and enzymes that generate second messengers. G proteins become inactivated by hydrolyzing GTP to GDP, which then permits the reassociation of the alpha subunit with the beta-gamma subunit complex.

Somatostatins Also called somatotropin-release-inhibiting factors. Refer to the 14-amino-acid (SS14) and 28-amino-acid (SS28) peptides which are produced by alternative proteolytic processing from a single 92-amino-acid precursor, called prosomatostatin.

Somatostatin receptors (sst receptors) comprise a family of five-membrane receptors which bind the neuroendocrine peptides somatostatin and cortistatin. These receptors exhibit the seven-transmembrane domain topology typical of G-protein-coupled receptors (GPCRs) and signal primarily through pertussis-toxin-sensitive G proteins. The different sst receptor subtypes are found in specific endocrine and exocrine tissues, including the pituitary and the pancreas, in addition to being widely distributed in the central and peripheral nervous systems and the gastrointestinal tract. They have important physiological roles in inhibiting hormone secretion, particularly the secretion of growth hormone, insulin, glucagon, and gastrin, inhibiting exocrine secretion by the pancreas and stomach, and modulating neuronal excitability and smooth muscle contraction. Many neuroendocrine tumors express high levels of sst receptors and, because of their ability to inhibit tumor-cell secretion and reduce tumor growth, somatostatin analogs are now used to target these receptors both for cancer therapy and diagnosis.

Physiological Sst Receptor Ligands

Somatostatin originally called somatotropin-release-inhibiting factor (SRIF) was discovered serendipitously over 30 years ago while investigators were hunting for the brain peptide responsible for stimulating the release of growth hormone, also called somatotropin. Surprisingly, they found that extracts of the hypothalamus, a specialized brain region which regulates pituitary hormone secretion, inhibited rather than stimulated the secretion of growth hormone. Using this inhibition as an assay, Guillemin and Schally and their co-workers purified the active factor from hypothalamic extracts and identified the 14 amino acid form of somatostatin, a discovery which contributed to their receiving the Nobel prize in 1977 for studies of hormone production in the brain.

Somatostatins are cyclic peptides that exist in two biologically active isoforms, 14 (SS14) and 28 (SS28) amino acids in length, and are produced by alternate proteolytic processing from a common precursor of 116 amino acids generated from

a single gene. These cyclic peptides are synthesized by specific endocrine, gastrointestinal, immune, and neuronal cells, as well as some tumors, and act either locally as paracrine, autocrine, or neuronal modulators or through the blood stream as hormones. Recently, the somatostatin gene has been shown to encode another peptide of 13 residues named neuronostatin, which is structurally unrelated to the two somatostatin isoforms. The variable amounts of neuronostatin and somatostatin produced in different tissues indicate differential and regulated processing of these peptides from the same precursor.

In addition to the peptides derived from the SS gene, the complementary DNA for a somatostatin-related peptide, cortistatin, was discovered in the process of characterizing region-specific rat brain messenger RNAs (mRNAs). Cortistatin was named for its predominant expression in the brain cortex and its ability to depress cortical neuronal activity. Like somatostatin, cortistatin is also synthesized as a precursor and is proteolytically processed into two biologically active products: a short (rat CST14 and human CST-17) and an amino-terminally extended (CST-29) form. Although cortistatin is produced from a different gene than somatostatin, the two peptides have 10 of their carboxy terminal 14 amino acids in common (Figure 1). Cortistatins are not only produced primarily by neurons in the central nervous system (CNS) but also have recently been found in immune cells, lymphoid tissues, bone marrow, and the pancreas.

Because all forms of somatostatin and cortistatin bind to the different sst receptor subtypes (sst's) with similar high affinities it is not surprising that the peptides share many functional properties. However, they also produce some distinct biological effects. For example, intracerebroventricular injection of cortistatin in rats increases slow-wave sleep but not rapid eye movement (REM) sleep whereas somatostatin injection increases REM sleep. Thus, the recent identification of a human cortistatin-selective GPCR that does not bind somatostatin (MrgX2 or Mas-related GPCR member X2, MRGPRX2) fulfills prior predictions for the existence of distinct cortistatin-specific receptors. However, this receptor binds a number of other apparently unrelated neuropeptides, such as proadrenomedullin

N-terminal peptide, so its physiological importance for cortistatin function is unclear. The specific roles of individual sst receptor subtypes as well as cortistatin-specific receptors in mediating particular physiological actions of these peptides remain an area of active investigation.

Biochemical and Molecular Characterization of Sst Receptors

Sst Receptor Subtypes

Five sst receptor genes, located on different chromosomes, have been identified and named *sst1–sst5* in the order of their discovery (Table 1). The coding regions of *sst1*, *sst3*, *sst4*, and *sst5* all occur within a single exon. However, in some mouse and rat tissues, the mRNA for *sst2* undergoes alternative splicing at the 3' end, producing two protein products. The more common *sst2A* variant is the product of the unspliced mRNA whereas the *sst2B* variant contains an alternative exon that encodes a different and shorter receptor carboxy-terminus. In contrast to rodents, the *sst2A* isoform is expressed almost exclusively in humans.

Figure 1 Structure of mammalian somatostatin-14 and human cortistatin-17. The amino acids in the red circles are required for high-affinity binding to somatostatin receptors. The amino acid differences between the two peptides are shown by the blue circles.

Sst receptors belong to the GPCR family and are predicted to contain seven- α -helical-transmembrane domains. Receptors for somatostatin have been cloned from a variety of mammals as well as from several nonmammalian species, including a number of fish. The human sst receptors exhibit between 40% and 57% amino acid identity with each other and sequence identity among the rat, mouse, and human orthologs of each receptor subtype is even higher. The greatest sequence similarity between sst receptor subtypes occurs within the transmembrane domains and hence these domains are thought to be involved in ligand binding. However, some extracellular loop residues have been shown to affect receptor subtype selectivity. Sequence differences in the intra- and extracellular domains appear to be responsible for the unique signaling and trafficking properties of individual sst receptor subtypes.

Based on sequence similarity, sst receptors have been subdivided into two groups: *sst1* and *sst4* receptors form the SRIF1 subgroup and *sst2*, *sst3*, and *sst5* constitute the SRIF2 subgroup. In addition to a closer phylogenetic relationship (Figure 2), members of each group share several functional properties including their affinity for short synthetic somatostatin analogs, such as octreotide and lanreotide, and sensitivity to agonist-induced receptor internalization (Table 1).

The GPCRs most closely related to the sst receptor family are GPR7 and GPR8, which encode receptors for two paralogous brain peptides neuropeptide B (NPB) and neuropeptide W (NPW) (Figure 2). The next most closely related gene family encodes the opioid receptors. The putative cortistatin receptor MrgX2 as well as the Urotensin II receptor (UR2R, GPR14) are more distantly related but share significant sequence identity with the sst receptor family.

Sst Receptor Structure

Sst receptors contain many of the structural features characteristic of GPCRs including consensus sites for asparagine-linked glycosylation within the amino-terminus and multiple Ser and Thr phosphorylation sites in the intracellular loops and carboxy-terminal tail (Table 1). All sst receptor subtypes except *sst3* also contain a conserved Cys residue in the carboxy-terminal region which provides a site for receptor palmitoylation although palmitoylation has yet to be demonstrated biochemically for any of the sst subtypes. However, *sst1*, *sst2*, *sst3*, and *sst5* are known to

Figure 2 Sequence relationships between somatostatin receptors and closely related peptide receptors. The dendrogram was generated with the Clustal W program using MacVector's default parameters to align the peptide sequences. Human sequences were used in all cases and were obtained either from SwissProt or RefSeq. Somatostatin receptors: hsst1, P30872; hsst2A, P30874; hsst3, P32745; hsst4, P31391; hsst5, P35346. Cortistatin receptor: MrgX2, NP_473371. Opioid receptors: KOR-1, P41145; MOR-1, P35372; DOR-1, P41143; and KOR-3, P41146. Neuropeptide B/W receptors NPBWR-1 or GPR7, P48145; and NPBWR-2 or GPR8, P48146. The plot shows that hsst1 and hsst4 form one subgroup and hsst2, hsst3, and hsst5 form a second subgroup within the somatostatin receptor family.

be glycosylated from the observation that treatment of these receptors with peptide-N-glycosidase F, an enzyme which catalyzes the cleavage of N-glycosidically linked carbohydrate chains from asparagine, causes a large decrease in their apparent molecular weights. Such a shift in molecular weight was not observed for sst4, either because it is not glycosylated or because glycosylation at its single consensus site does not significantly affect its apparent molecular weight.

Receptor phosphorylation, a covalent modification important for GPCR regulation and signaling, has been examined biochemically for some but not all sst receptor subtypes. Somatostatin stimulates the incorporation of $^{32}\text{PO}_4$ into sst1, sst2A, and sst3 receptors and protein kinase C activation also increases phosphorylation of the sst1 and sst2A subtypes. However, phosphorylation of sst4 was not detected following agonist stimulation and sst5 phosphorylation has not been investigated biochemically.

Using phospho-site-specific antibodies seven Ser and Thr residues in the sst2A receptor C-terminus were shown to be phosphorylated within minutes of agonist stimulation. These complex phosphorylation reactions appear to be catalyzed by members of the GPCR kinase family. The sst2A receptor is also phosphorylated on at least two Ser residues by protein kinase C and this phosphorylation is independent of agonist occupancy. Phosphorylation of other sst receptor subtypes has not been studied in detail and we know little about the enzyme mechanisms involved.

Pharmacology of Sst Receptor Subtypes

The native somatostatin peptides exhibit little selectivity among the different receptor subtypes and are rapidly degraded in plasma (half-time <3 min). Thus, analogs with increased metabolic stability and greater receptor specificity have been developed for therapy.

The earliest pharmaceuticals to target sst receptors were short peptides, 6–8 amino acids in length, containing amino acids 7–10 of SS14, the region required for receptor binding (Figure 1). These agonists, including octreotide (SMS201-995), lanreotide (BIM-23014), and seglitide (MK-678), also contain D-amino acid substitutions and carboxy- or amino-terminal modifications to increase their resistance to proteolysis. All three of these truncated peptides bind selectively to the SRIF1 group of receptors, exhibiting subnanomolar affinity for sst2 and nanomolar affinities for sst3 and sst5 (Table 1). Further, octreotide, like somatostatin, does not bind to the MrgX2 cortistatin receptor. Presently, octreotide or lanreotide are used as standard-treatment options for patients with hormone-secreting pituitary adenomas and gastroenteropancreatic tumors and, in various formulations, comprise the only approved pharmaceuticals targeting sst receptors for cancer therapy.

In an effort to generate truly receptor subtype-specific analogs that are even more resistant to proteolytic degradation, Rohrer and co-workers at Merck screened combinatorial libraries to successfully identify the first highly selective, high-affinity, non-peptide agonists for each sst receptor subtype. Such reagents provide the possibility of oral bioavailability although nonpeptide sst agonists are yet to be approved for clinical use. Nonetheless, these specific compounds have proved to be valuable tools for identifying the physiological roles of individual sst receptor subtypes. The development of such nonpeptide somatostatin analogs may not only generate orally available drugs for current indications but also provide new therapies for diseases that require drug access to the CNS.

The recognition that many tumors concomitantly express several sst receptor subtypes has stimulated a search for stable somatostatin analogs that are less receptor selective. The hexapeptide analog SOM230 (Pasireotide) shows quite high affinity for four of the five sst receptor subtypes (Table 1) and is in late-phase clinical development. The nanopeptide analog KE108 appears to be truly universal because it binds to all five sst subtypes with nanomolar affinity. Because of their excellent metabolic stability these broad-spectrum agonists have significant therapeutic potential. Unexpectedly, however, both SOM230 and KE108 behave as biased agonists at the sst2A receptor, the most widely expressed sst receptor subtype in human tumors. Thus, they are full agonists mimicking somatostatin's action to inhibit cyclic adenosine monophosphate (cAMP) production, whereas they fully antagonize sst2A receptor signaling to other pathways, such as ERK phosphorylation and regulation of intracellular calcium. In addition, these analogs are less effective than somatostatin at inducing receptor internalization. The differences between the actions of full agonists, like octreotide, and biased agonists, like SOM230, at the sst2A receptor is likely to have therapeutic consequences, but these remain to be investigated in detail.

The first sst receptor antagonist CYN-154806 was described in 1996 and showed strong selectivity for the sst2 receptor subtype. Since then specific antagonists have been identified for all five sst receptors, although none are used clinically.

In addition to their therapeutic applications, analogs of somatostatin have been developed to localize and stage sst-receptor positive tumors *in situ*. The radiolabeled derivatives used for tumor diagnosis contain a chelating group covalently attached to a stabilized somatostatin peptide, such that its

receptor-binding properties are not compromised. The chelating group is then bound to a short-lived radioisotope, such as the gamma emitter ^{111}In , and injected into patients. After 24 h, accumulation of the radiolabel can be visualized in tumors expressing high levels of sst receptors by gamma camera scintigraphy, thus permitting localization of the tumors and their metastases. The analog in current clinical use is an indium-labeled octreotide derivative, [^{111}In -DTPA-D-Phe¹, Tyr²]octreotide, (OctreoScan) and hence is selective for the SRIF1 group of sst receptors, showing most-sensitive detection of sst2-expressing tumors. Although this analog, therefore, cannot be used to localize tumors expressing sst1 or sst4 receptors, new radiolabeled somatostatin analogs are currently being developed to improve both the sensitivity and breadth of this approach.

Sst Receptor Signaling

Sst receptors regulate a number of diverse signaling effectors, including adenylyl cyclase, phospholipases C and A2, calcium and potassium channels, protein and lipid kinases, and tyrosine and serine/threonine phosphatases. All sst receptors inhibit adenylyl cyclase via pertussis toxin-sensitive G proteins and, thus, decrease intracellular cAMP. However, other signal transduction pathways modulated by sst receptors depend on both the receptor subtype and the environment provided by the target cell, as well as the nature of the agonist.

The mechanism by which sst receptors inhibit secretion in endocrine cells and neurons is understood in some detail. In addition, to reducing intracellular cAMP levels, several sst receptors have been shown to reduce intracellular calcium levels in excitatory cells also via pertussis toxin-sensitive G proteins. The reduction in cytosolic calcium can result either from a stimulation of potassium channels, which hyperpolarizes the cell membrane and thereby decreases calcium influx through voltage-dependent calcium channels, or from direct calcium channel inhibition. The resulting decrease in intracellular cAMP and calcium concentrations together contribute to the inhibitory action of somatostatin on secretion: when either signaling pathway is blocked, the magnitude of somatostatin's inhibitory effect is reduced.

Somatostatin stimulates contraction of intestinal smooth muscle cells by inhibiting adenylyl cyclase and activating phospholipase C- β 3 via the alpha and beta-gamma subunits, respectively, of pertussis toxin-sensitive G proteins. The activated phospholipase catalyzes the hydrolysis of the membrane lipid phosphatidylinositol 4,5-bisphosphate to form the second messengers inositol trisphosphate (IP_3) and diacylglycerol. The binding of IP_3 to receptors on the sarcoplasmic reticulum results in the release of calcium from intracellular stores producing a rise in cytosolic calcium concentrations. The released calcium forms a complex with the protein calmodulin and this complex then activates myosin light-chain kinase (MLCK) to phosphorylate the light chain of myosin leading to smooth muscle contraction. Because protein kinase A (PKA) decreases the sensitivity of MLCK to calcium, somatostatin inhibition of cAMP formation facilitates the calcium effect by reducing the activity of PKA. These pathways are also activated by somatostatin in aortic vascular smooth muscle cells. Interestingly, somatostatin does not activate phospholipase C- β 3 in pituitary cells, even though the levels of this enzyme in the

pituitary appear to be similar to that in smooth muscle cells. The explanation for the signaling differences in these tissues remains to be elucidated, but could be due to differences either in the sst subtypes or the signaling machinery present.

In endothelial cells, somatostatin inhibits cell migration, stress fiber assembly, and cytoskeletal reorganization produced by thrombin and other stimulators. In humans, these effects are mediated by the sst1 receptor and have been implicated in somatostatin's antiangiogenic actions. Although the molecular steps involved remain to be identified, the mechanism includes an unusual, pertussis toxin-independent inhibition of Rho, a low-molecular-mass guanosine triphosphatase which plays a central role in regulating cytoskeletal organization.

The mechanisms by which somatostatin inhibits cell proliferation and stimulates apoptosis have garnered intense interest yet remain poorly understood at least partly because they vary in the different cell types in which they have been examined. In most, although not all, cells somatostatin activates the mitogen-activated protein kinase (MAPK) pathway and increases ERK1/2 phosphorylation by both pertussis toxin-sensitive and -insensitive mechanisms. However, such activation is often observed whether somatostatin inhibits or stimulates cell proliferation. Thus, some of the other effectors regulated by sst receptors must contribute to the final biological response. For example, in pancreatic acinar cells expressing sst2 receptors endogenously, somatostatin-induced growth arrest involves enhanced expression of the cyclin-dependent kinase inhibitor p27Kip which results from inhibition of the phosphatidylinositol-3-kinase (PI3K) pathway. By contrast, in sst2-transfected CHO cells, somatostatin induction of p27Kip appears to be dependent on stimulation rather than inhibition of PI3K. These, and other signaling pathways involved in cell proliferation and apoptosis are currently under investigation in order to elucidate the clinically important actions of somatostatin to inhibit tumor growth.

In summary, most, but not all, signaling by sst receptors involves the pertussis toxin-sensitive Gi/Go family. However, depending on the sst receptor subtype, the cellular environment, and the analog utilized, a spectrum of signaling pathways can be activated. The link between the different effectors regulated by sst receptors and particular biological responses is understood for some but far from all of somatostatin's actions.

Sst Receptor Regulation

Changes in sst receptor responsiveness during somatostatin exposure vary dramatically between tissues, depending both on the response being measured and on the nature of the target cell. In some instances, desensitization occurs within minutes following initiation of somatostatin treatment, whereas in others no desensitization is detected even after years of somatostatin analog exposure. For example, in chick sympathetic neurons, somatostatin inhibition of N-type Ca currents desensitize with a half-time of 3 min. In contrast, desensitization to pharmacologic doses of the somatostatin analog octreotide does not occur for months or years of therapy for pituitary tumors. The molecular basis for such dramatic differences in sst receptor regulation in different cell types remains poorly understood.

Nonetheless, studies in cultured cells have begun to elucidate the mechanisms by which individual sst receptor subtypes are regulated. As for many GPCRs, hormone treatment leads to the rapid phosphorylation of several sst receptor subtypes (Table 1). Interestingly, however, this phosphorylation appears to have different consequences for the different sst receptors. For example, in CHO cells, although both sst1 and sst2A receptors are phosphorylated and desensitized within minutes following somatostatin exposure, only the sst2A receptor is rapidly internalized. As the sites of sst2A receptor phosphorylation have been identified, site-directed mutagenesis has provided insight into the biological importance of the complex pattern of sst2A receptor phosphorylation. In this receptor, Thr phosphorylation sites are required for rapid agonist-stimulated sst2A receptor internalization and arrestin recruitment. By contrast, Ser phosphorylation sites are not required for arrestin recruitment and do not affect receptor endocytosis. However, Ser phosphorylation is important for sst2A receptor desensitization. The manner in which protein kinase C-mediated phosphorylation at specific receptor residues changes sst2A receptor function remains to be determined. The biochemical details and role of receptor phosphorylation in the regulation of sst1, sst3, and sst5 receptors remain to be investigated.

Although large gaps remain in our understanding of sst2A receptor regulation, the outlines of the processes involved are slowly becoming clear. Furthermore, the insights obtained from studies in cultured cells appear to apply to the behavior of sst2A receptors *in vivo*. For example, the sst2A receptor has been shown to be phosphorylated and internalized *in situ* in human tumors. As the molecular components of sst receptor desensitization are characterized, it will be interesting to determine how their functions differ in cells that are sensitive or resistant to somatostatin-analog-induced desensitization.

Conclusions

The five known sst receptors play important physiological roles in the regulation of the endocrine, neuronal, gastrointestinal, and immune systems. In addition, they are recognized to be important targets in the diagnosis and treatment of neuroendocrine tumors.

Although a great deal remains to be learned about many of somatostatin's biological functions, recent studies with knock-out mouse models lacking expression of somatostatin or cortistatin or one of the five sst receptor subtypes have begun to delineate the biological importance of the individual endogenous ligands and their receptors. Interestingly, all these knock-out models are viable and fertile. In fact, they usually exhibit no major overt abnormalities with the exception of the sst4 null mouse, which develops spontaneous seizures. However, specific defects have been described in neuronal, endocrine, and gastrointestinal functions with many of the somatostatin ligand and receptor knockout models. Although these studies have provided substantial insights into the importance of individual sst receptor subtypes, they have also revealed species-specific differences in the functions of these receptors. Fortunately,

studies of sst receptors in different species can now take advantage of the many receptor-specific agonists and antagonists that have become available and are likely to provide additional insight into the normal roles played by this physiologically and clinically important GPCR family. Our increasing molecular understanding of sst receptor signaling and regulation will undoubtedly facilitate the development of novel therapeutic interventions targeting this receptor family.

Glossary

Haploinsufficiency A locus shows haploinsufficiency when the amount of the gene product produced by a single allele is not sufficient to achieve a normal phenotype.

Paraplegia Paralysis of both lower limbs.

Spasticity Muscular weakness associated with increased stiffness and overactive reflexes.

Hereditary spastic paraplegia (HSP) is a group of neurodegenerative diseases characterized by weakness and spasticity of the lower limbs, loss of the vibratory sense, and urinary urgency. In 1983, Harding classified HSP in pure forms, when the symptoms are restricted to lower limbs weakness and spasticity, and in complicated forms, when the clinical picture is associated to a variety of neurological symptoms. These may include cerebral and cerebellar atrophy, optic atrophy, peripheral neuropathy, dementia, retinitis pigmentosa, and amyotrophy. Age of onset is extremely variable, with a few forms arising in childhood, and most cases between 20 and 40 years of age. Usually, the later the onset of the disease, the faster is the progression of its course. Although HSP is an invalidating disease, it never causes shortening of the life span of patients.

Neuropathology

HSP is characterized by the retrograde degeneration of the longest axons of the central nervous system (CNS): those of the crossed corticospinal tracts and of the fasciculus gracilis. In about half of the autopsic cases examined, the spinocerebellar tracts were also involved.

Axons of the corticospinal tracts arise from pyramidal neurons in layer V of the motor cortex and project through the internal capsule to reach the ventral surface of the medulla where they form two elongated swellings, the pyramids. These axons cross the midline at the junction between the bulb and the spinal cord and descend in the contralateral funiculus of the spinal cord. The crossed corticospinal tract conveys voluntary motor impulses to the secondary motor neurons located in the ventral horns of the spinal cord. The fasciculus gracilis is composed of the central branches of axons of pseudounipolar neurons located in dorsal root ganglia and ascend in the most medial part of the dorsal funiculus. These axons transmit deep sensory information from the lower extremities to secondary sensory neurons in the nucleus gracilis.

Characteristically, axonal degeneration in HSP involves preferentially the distal region of the axons. Degeneration of the corticospinal tracts is marked at lumbar levels and less pronounced at cervical levels. In most cases, the neuronal cell bodies are preserved. This pattern of axonal degeneration, also referred to as dying back, is slowly progressive and occurs

in several other conditions following a toxic, metabolic, or genetic insult.

Genetics

HSP is extremely heterogeneous from a genetic point of view. More than 40 different loci (listed SPG1–45) have been mapped at the time of writing. HSP can be transmitted as an X-linked, autosomal dominant, or autosomal recessive trait. In general, autosomal recessive HSPs are associated with a complicated phenotype, whereas autosomal-dominant forms tend to be pure. The molecular bases of the disease are also being unraveled at a quick pace. Nineteen HSP genes have been identified, thus providing clues on the cellular pathways underlying the disease. [Table 1](#) summarizes the current knowledge on the genetic bases of HSP.

Pathogenesis

The identification of several genes involved in HSP is beginning to shed light on the pathogenesis of this disorder. Although the known genes belong to different families and have distinct subcellular localizations, common pathogenic themes have emerged ([Figure 1](#)). The corticospinal neurons have extremely long axons that can reach the length of more than 1 m in humans and contain more than 99% of the cytoplasm of the cell. Development and maintenance of these neurons depend on efficient transport of organelles, molecular cargoes, and synaptic vesicles from the cell body to the distal tip of the axon, and back to the cell body. Transport processes are mediated by motors along cytoskeletal tracks and are coupled to membrane-trafficking events. The vast majority of HSP genes for which we have functional information are involved in different aspects of cell trafficking, such as microtubule (MT) dynamics, anterograde transport on microtubular tracks, endoplasmic reticulum (ER) morphogenesis, or endosomal trafficking. These processes require energy and are supported via coordinated movement of mitochondria along axons. Another group of HSP genes is indeed involved in mitochondrial quality control. Finally, axonal homeostasis strictly depends on myelin integrity, and an emerging category of HSPs is caused by mutations in

proteins important for myelin–axonal interaction. Based on the current data, a tentative classification of known HSP genes in functional groups can be put forward.

Genes Involved in Cellular Trafficking Events

SPG4/spastin

SPG4 is the gene most commonly mutated in AD-HSP (~40% of cases), and its functional characterization clearly emphasizes the importance of cytoskeletal remodeling for axonal homeostasis. *SPG4* encodes spastin, an ATPase belonging to the AAA

(ATPases associated with diverse cellular activities) family. Spastin is involved in MT severing, a process by which long MTs can be fractured into shorter tracks. Spastin forms a ring-shaped hexamer containing a central pore and six radiating arms that dock onto the MTs. Structural data obtained using *Drosophila* spastin put forward a model by which spastin pulls the C-terminus of tubulin through its central pore generating a mechanical force that destabilizes tubulin–tubulin interactions within the MT lattice. MT severing plays an important role during meiosis and mitosis to release MTs from the centrosome and is thought to be essential in neurons, where the capacity of

Figure 1 Schematic representation of a motor neuron, with the subcellular localization of the known HSP genes.

an MT to move is strictly related to its length. Spastin is indeed enriched in the centrosome, in the cytokinesis structure midbody, and in growth cones and branching points of neurons, all regions characterized by extensive cytoskeletal remodeling. It is, therefore, an attractive hypothesis that HSP, due to *SPG4* mutations, arises through disturbances of the dynamics of MTs in the long central motor axons.

The relevance of spastin function for axonal development and maintenance has been demonstrated both *in vitro* and *in vivo*. Spastin plays a role in the formation of axonal branches and in axonal development. Spastin knockdown in *Drosophila* by RNA interference (RNAi) caused defects in synaptic growth and neurotransmission due to an aberrantly stabilized MT cytoskeleton. These phenotypes could be ameliorated by administration of vinblastine, an MT-destabilizing drug. A depletion of presynaptic MTs was observed in null and hypomorph deletion spastin mutants. Dramatic defects in motor axon outgrowth and extensive apoptosis were found in the zebrafish, when morpholino antisense oligonucleotides were used to knock down spastin in the developing embryo. Finally, homozygous *Spg4*^{-/-} mice displayed a late-onset motor deficit associated with focal axonal swellings in the lumbar spinal cord with accumulation of organelles and cytoskeletal components, caused by severe reduction of anterograde and retrograde axonal transport.

Spastin MT-severing activity is targeted to specific cell compartments through the ability of spastin to interact with a variety of molecules via its N-terminal region. The N-terminal region of spastin can vary in length, through usage of two AUG codons in the first exon, and alternative splicing of exon 4, thus conferring potential for isoform-specific interactions. Indeed, spastin can be recruited in an isoform-specific pattern to endosomes or the early secretory pathway. The full-length spastin isoform is localized to the early secretory pathway, either on ER domains or on vesicles of the ER-to-Golgi intermediate compartment, while the short form of spastin (lacking the N-terminal 86 amino acids) can be strongly and preferentially recruited to endosomes. Notably, a number of spastin-interacting molecules link

spastin function to membrane-trafficking events. The full-length spastin isoform interacts with atlastin-1, REEP-1, and reticulon-1, three ER morphogens (see below). Spastin also interacts with the endosomal sorting complex required for transport (ESCRT)-III protein CHMP1B through the N-terminal MT interacting and trafficking (MIT) domain. The ESCRT machinery plays important roles in membrane cleavage events during multivesicular body formation and cytokinesis. CHMP1B is required for the recruitment of spastin to the midbody, thus suggesting coordinated MT severing and membrane abscission.

SPG3A/atlastin-1

The second most common gene involved in autosomal-dominant pure HSP (approximately 10% of the cases) has been linked to the *SPG3A* locus and found to encode one member of the atlastin family, atlastin-1. Atlastins belong to the dynamin family of large guanosine triphosphatases (GTPases), but are characterized by two closely spaced transmembrane segments near their C-termini. Atlastin-1 localizes to the ER, ER-to-Golgi intermediate compartment, and to the *cis*-Golgi apparatus and interacts through the transmembrane segments with members of the reticulon and DP1/Yop1p families. Both of these protein families are involved in shaping the tubular ER. Overexpression of a GTPase-inactive version of atlastin-1 or the cellular depletion of atlastin family proteins induces the formation of long unbranched ER tubules, while atlastin-1 overexpression leads to a drastic alteration of the ER morphology. In the *Drosophila* system, it was shown that *trans*-oligomeric complexes of atlastin promote homotypic fusion of ER membranes in a guanosine triphosphate (GTP)-dependent fashion. These studies suggest a model in which the reticulons and Yop1p proteins promote ER membrane tubulation, while a conformational change in atlastin, occurring on GTP hydrolysis, affects branching of the ER tubules by promoting homotypic membrane fusion. It is possible that spastin couples these membrane modeling events to MT regulation events that are also important for ER morphogenesis.

SPG31/REEP1

The hypothesis that ER morphogenesis plays an important role in the pathogenesis of HSP is further emphasized by the implication of the receptor-enhancing protein 1 (REEP1) protein in the third most common autosomal-dominant form of HSP. Although originally identified as a mitochondrial protein, REEP1 is a mammalian homolog of the DP1/Yop1p family. Similar to their yeast counterpart, mammalian REEP proteins are required for ER network formation *in vitro*. REEP1 interacts with the MTs through its C-terminal region and promotes ER alignment along the MT cytoskeleton. Remarkably, REEP1 interacts with both the long spastin isoform and atlastin-1 via hydrophobic hairpin domains in each of these proteins. Thus, at least three proteins involved in pure HSP – spastin, atlastin, and REEP1 – are likely to have a directly related function in ER morphogenesis and its interaction with the cytoskeleton.

SPG10/KIF5A

One of the best examples of the pathogenic role of impaired axonal transport in HSP comes from the identification of mutations in the gene encoding a specific neuronal kinesin heavy chain, KIF5A, in families with an autosomal-dominant pure form of HSP (SPG10). Kinesins are multisubunit complexes that work as motors for anterograde transport (from the cell body to the distal end of the axons) of membranous organelles and other macromolecular cargoes along MTs. KIF5A is abundantly expressed in neurons, where it is found in cell bodies, dendrites, and axons. Most of the KIF5A mutations that have been identified so far are missense mutations located in the kinesin motor domain. *In vitro* transport assays with purified motor domain mutants mixed with wild-type motors to mimic the situation in heterozygous HSP patients revealed that the presence of the mutant motors either slowed moving cargo populations or led to reduced MT binding affinity. In both cases, the gross cargo flux to the synapse might be reduced, either by a simple delay of transport or because of competition of MT-binding deficient motors with wild-type motor for cargo-binding sites.

SPG20/spartin

SPG20 is the gene involved in Troyer syndrome, an autosomal recessive form of HSP complicated by dysarthria, distal amyotrophy, mild developmental delay, and short stature, occurring with high frequency in the Amish population. The SPG20 protein product, spartin, shares homology in the N-terminal region with spastin within the MIT domain (see above). This has led to the hypothesis that spartin may be somehow involved in endosome trafficking. Indeed, endogenous spartin can be recruited to endosomes under some circumstances, such as epidermal growth factor (EGF) stimulation or expression of a dominant negative form of Vps4. Spartin is required for efficient EGF receptor degradation. However, the cell role of spartin appears more complex. A certain amount of endogenous spartin localizes to lipid droplets, and both overexpression and downregulation of spartin increase the formation of lipid droplets. Furthermore, some authors have localized a fraction of spartin on mitochondria. Spartin is monoubiquitinated and interacts with the ubiquitin ligase WW1. A full explanation of spartin role in HSP will require the elucidation of its function at different subcellular sites and the relevance of interaction with the ubiquitin ligase WW1.

SPG6/NIPA1

Mutations in the NIPA1 gene cause autosomal-dominant HSP. NIPA1 encodes for a polytopic integral membrane protein, localized to the cell membrane and to endosomes. One study has suggested that NIPA1 is a functional magnesium transporter. NIPA1 mutations in HSP patients are all missense mutations, which affect trafficking of the protein through the secretory pathway and its trapping in the ER. Studies in mammalian overexpression systems and in *Caenorhabditis elegans* have suggested that the mutations might be pathogenic via induction of ER stress and an unfolded protein response. This mechanism has been, however, questioned by another study. By contrast, a role of NIPA1 in bone morphogenetic protein (BMP) signaling has been proposed. Experiments with the *Drosophila melanogaster* homolog of NIPA1, spichthyin, have demonstrated that spichthyin regulates BMP receptor trafficking. *Drosophila* larvae lacking spichthyin display distal axonal abnormalities characterized by neuromuscular junction overgrowth that can be rescued by genetic manipulations blocking BMP signaling. In mammalian cells, NIPA1 was shown to physically interact with type II BMP receptors and to promote their endocytosis and lysosomal degradation, thus affecting BMP signaling. NIPA1 mutations would be less efficient at promoting degradation of BMP receptors. Remarkably, the same study suggested that spastin and spartin, although with a still unknown mechanism, may also inhibit BMP signaling, thus suggesting a common pathogenic mechanism.

Other HSP Genes with Potential Endosomal Localization

Other HSP genes have been proposed to localize to compartments of the secretory pathway or to play a role in cell trafficking. Mast syndrome is an autosomal recessive complicated form of HSP associated with dementia, present at high frequency in the Old Order Amish population. The causative gene, SPG21, encodes an acid-cluster protein of 33 kDa (ACP33), renamed maspardin, which localizes to the endosomal/*trans*-Golgi network. Maspardin has been found to interact with the aldehyde dehydrogenase ALDH16A1, a component of the large family of ALDH proteins, which catalyze the irreversible oxidation of a wide spectrum of aliphatic and aromatic aldehydes during the metabolism of endogenous and exogenous compounds. Further studies are required to clarify the function of maspardin and the role of this interaction for HSP pathogenesis, but it is worth mentioning that another ALDH protein, ALDH3A2, is involved in Sjögren–Larsson syndrome, a disease characterized by the association of mental retardation, ichthyosis, and spastic paraparesis.

Mutations in spastizin (SPG15) and spatacsin (SPG11) result in complex forms of HSP characterized by thin corpus callosum, maculopathy, and cerebellar signs. Preliminary studies suggest that they are present in different cell compartments, including the ER. Spastizin carries a FYVE domain, a signature for binding to phosphatidylinositol 3-phosphate, a phospholipid found on endosomal membranes.

Proteins Involved in Lipid Metabolism

As already mentioned, two studies have suggested a role of spartin in the formation of lipid droplets. Another HSP protein

involved in lipid droplet biogenesis is seipin (SPG17/BSCL2). Complete loss of function of seipin causes congenital-generalized lypodystrophy type 2, a disease characterized by loss of adipose tissue associated with hypertriglyceridemia, insulin resistance, and diabetes. Yeast seipin is found at the ER lipid droplet junctions and is important for droplet morphology. Two missense mutations that affect glycosylation of seipin have been instead associated to dominant neurological phenotypes, such as HSP, Charcot-Marie-Tooth disease or distal hereditary motor neuropathy type V. The current hypothesis is that these mutations act with a gain-of-function mechanism by inducing an ER stress response.

The CYP7B1 cytochrome P450 enzyme, mutated in SPG5A, hydroxylates oxysterols and neurosteroids, such as dehydroepiandrosterone and pregnenolone. Hydroxylation reduces the biological activity of these substrates and facilitates their conversion to end products easily excreted from the cell bodies. A marked accumulation of 27-hydroxycholesterol was indeed found in both plasma and cerebrospinal fluid in patients with SPG5A, although the pathogenic significance is still unclear.

Neuropathy target esterase (NTE) was originally discovered as the primary target of organophosphorous compounds, poisoning of which causes a delayed paralyzing syndrome with degeneration of motor axons. Subsequent cloning of the gene disclosed that NTE is a member of the patatin-like phospholipase family. NTE is a resident protein of the ER and catalyzes hydrolysis of membrane-associated lipids, as lysophospholipids. It is also implicated in deacylation of phosphatidylcholine. Sustained elevation of phosphatidylcholine was observed in a conditional NTE knockout in which the protein was selectively removed in neurons. This biochemical phenotype was accompanied by progressive axonal swelling and degeneration in sensory and motor spinal tracts, resembling HSP.

Mitochondrial Proteins

SPG7/paraplegin

SPG7 encodes paraplegin, a 795-amino-acid protein highly homologous to two yeast metalloproteases of the AAA family, Yta10p (Afg3p) and Yta12p (Rca1p). Like its yeast homologs, paraplegin has an N-terminal mitochondrial leader sequence and two transmembrane domains that anchor the protein to the inner mitochondrial membrane. Paraplegin is composed of two functional domains: an ATPase domain typical of proteins of the AAA family (ATPases associated with diverse cellular activities) and a proteolytic domain with a consensus metal-binding site.

The yeast Yta10p and Yta12p assemble to form a high-molecular-weight complex of about 1 MDa, the *m*-AAA protease, which is embedded in the inner mitochondrial membrane but exposes proteolytic sites to the mitochondrial matrix (hence the prefix *m* in the name). The *m*-AAA protease ensures protein quality control for inner membrane proteins, by guaranteeing the removal of nonassembled or misfolded proteins, and mediates the processing of specific mitochondrial substrates, such as the mitochondrial ribosome component Mrp132. Yeast cells that lack the *m*-AAA protease are unable to grow on nonfermentable substrates and exhibit deficiencies in the synthesis of mitochondrially encoded polypeptides.

Paraplegin co-assembles with the highly homologous AFG3L2 protein in human mitochondria to form a high-molecular-weight complex very similar to the one described in yeast. The human AFG3L2 protein is also capable of forming functional homo-oligomeric complexes. Remarkably, AFG3L2 is involved in a dominant form of cerebellar ataxia, SCA28. Mammalian *m*-AAA hetero-oligomeric or homo-oligomeric proteases complement the respiratory phenotype of Yta10p-Yta12p-deficient yeast, indicating functional conservation across species. In addition, the mammalian *m*-AAA protease has been implicated in proteolytic maturation of OPA1, which is involved in inner mitochondrial membrane fusion, cristae remodeling, and apoptosis, and is mutated in an autosomal-dominant form of optic atrophy. This opens up the possibility that deficiency of *m*-AAA protease subunits might cause alteration of mitochondrial dynamics, thus affecting the distribution and transport of these organelles.

Paraplegin-deficient mice recapitulate the human disease, being affected by a late-onset progressive distal axonopathy, characterized by axonal swelling and degeneration, due to the accumulation of membranous organelles and neurofilaments, suggesting that axonal transport is impaired. The first ultrastructural pathological sign that can be observed in paraplegin-deficient mice occurs several months before any evidence of axonal swelling and degeneration and consists in the appearance of abnormal mitochondria first in synaptic terminals and then in the distal regions of the long spinal axons that will later on undergo degeneration. Abnormal mitochondria include hypertrophic mitochondria, gigantic mitochondria, and mitochondria with disrupted or abnormal organization of cristae. This mitochondrial phenotype correlates with the onset of a measurable neurological impairment of the paraplegin-deficient mice on the rotarod apparatus and is therefore the primary trigger of the pathological process. Remarkably, mitochondrial abnormalities and axonal degeneration in the peripheral nerve could be partially rescued by intramuscular delivery of paraplegin cDNA via adeno-associated viral vectors.

Biochemical studies on fibroblast cell lines obtained from HSP patients with SPG7 mutations, and on mitochondria from mice with reduced dosage of *m*-AAA protease subunits, found a reduction of complex I activity, probably due to decreased stability of the assembled complex, and an increased sensitivity to oxidative stress, suggesting a potential mechanism for mitochondrial damage. This could be especially important in mitochondria located in nerve terminals where high energetic demands and increased concentration of free radicals are present.

SPG13/HSP60

The Hsp60 protein belongs to a conserved subgroup of chaperone proteins, termed chaperonins, which promote protein folding in the mitochondrial matrix, often in cooperation with the co-chaperonin Hsp10. The first Hsp60 mutation identified in a HSP family results in the V72I substitution. An elegant complementation assay performed in *Escherichia coli* showed that only wild-type Hsp60, but not Hsp60-V72I, together with the co-chaperonin Hsp10, can support the growth of bacteria in which the homologous chromosomal *groESgroEL* chaperonin genes have been deleted, indicating that the V72I mutant is

functionally inactive. It is unclear whether this mutant leads to haploinsufficiency through the formation of functionally inactive mixed chaperonin rings made up by both normal and mutated subunits, or may exert a genuine dominant-negative effect. The frequency of mutations in HSPD1 in HSP is very low. So far, only one other family has been reported in which a different missense mutation (Q461E) caused the disease with low penetrance. A recent study has suggested a role of Hsp60 as genetic modifier for the most common form of HSP due to spastin mutations.

Genes Involved in Myelin–Axonal Interactions

Disruption of intimate glia to axon interactions underlies the axonal degeneration observed in SPG2 patients. SPG2 maps to Xq22 and results from mutations in the proteolipid protein (PLP), one of the major protein components of myelin in the CNS. PLP is a four-helix spanning membrane protein that stabilizes the structure of the CNS myelin, by forming the intraperiod line. SPG2 comprises both pure and complicated forms of HSP and is allelic to the severe hypomyelinating Pelizaeus–Merzbacher disease (PMD). A genotype–phenotype correlation between the nature of PLP mutation and the severity of the clinical picture has been described. In general, the milder phenotypes, such as pure spastic paraplegia, are observed when the gene mutations lead to the formation of protein products that are still able to transverse the secretory pathway and reach the cell surface. Interestingly, these mutants exhibit impaired cholesterol binding and decreased association with lipid raft microdomains. Surprisingly, knockout mice with complete absence of PLP assemble compact myelin sheaths, but subsequently develop widespread axonal swelling and degeneration, most likely secondary to impaired axonal transport. It is still a mystery how the correct expression of PLP in oligodendrocytes provides support for myelinated axons. The future identification of putative signaling molecules would probably lead to a better understanding of this pathological cascade.

The strict relationship between myelination and axonal maintenance is further supported by the finding of mutations in the fatty acid 2-hydroxylase (FA2H) gene in patients with the complicated HSP form SPG35. FA2H is found in oligodendrocytes and is responsible for the first step of incorporation of α -hydroxylated galactosyl ceramides (GalCer) into myelin using free fatty acid as substrates. GalCer represent about 20% of mature myelin lipid. Mice deficient for FA2H display a late-onset axonal degeneration phenotype associated to myelin degeneration.

Recessive mutations in GJC2, the gene encoding the gap junction protein connexin47, cause Pelizaeus–Merzbacher-like disease. However, a recent study has identified one family carrying a novel recessively inherited mutation associated to a milder phenotype of complicated HSP. Gap junctions formed

of connexin47 and connexin43 play an important role for myelin maintenance.

Finally, another HSP gene that could have a role in myelin function is SLC33A1 (SPG42). This gene encodes an acyl-CoA transporter, a multiple transmembrane protein in the ER that transports acyl-CoA from the cytoplasm to the Golgi/ER where it serves as substrate of acetyltransferase that modifies the sialyl residues of gangliosides and glycoproteins. Gangliosides are highly expressed in the brain and play an important role in axon-myelin stability.

Developmental Genes

HSP may result from mutations in genes involved in the development of the corticospinal tracts. This is the case of SPG1, which has been linked to mutations in the cell adhesion molecule L1CAM. Consistently, neuropathological studies found absent or severely reduced pyramids in patients. In this form of HSP, spastic paraplegia begins in the first two decades of life, with delayed acquisition of motor milestones and slow progression of symptoms. Although this form may manifest as pure HSP, it is more often observed in association with a complex disorder, referred to either as mental retardation, adducted thumbs, spasticity and aphasia (MASA) syndrome or as corpus callosum hypoplasia, mental retardation, adducted thumbs, spastic paraplegia, and hydrocephalus (CRASH) syndrome. L1CAM is a transmembrane glycoprotein, which is expressed during development on the surface of long axons and growth cones, including those of the corticospinal tracts. L1 mediates cell adhesion, neurite outgrowth, axon pathfinding, and fasciculation through homophilic and heterophilic binding with a variety of extracellular and transmembrane molecules, and plays an important role in mediating guidance of corticospinal axons through the pyramidal decussation.

Glossary

Brown converter An electrical chopper developed by the Leeds and Northrup Company that had very little contact potential variation.

Cytochrome oxidase The terminal enzyme of most oxygen-using systems.

Dual-wavelength spectrophotometer A spectrophotometer with time shared to adjacent wavelengths in order to minimize the effect of scattering changes upon absorbance changes, because scattering varies very slowly with wavelength, while cytochrome absorption varies sensitivity with wavelength.

DuBridge electrometer (DU) A remarkable use of the suppressor grid of the pentode to control electron flow with very high input impedance, affording the basis of the Beckman pH meter and spectrophotometer.

Electron tunneling The transfer of electrons between two proteins at a distance without collision of their active sites.

Flavoprotein A widely spread pigment, but in this article the prosthetic group of ketoglutarate and pyruvate dehydrogenase.

Mercury arc A very useful light source for biological studies, which gives light at exactly the correct wavelength for hemoglobin and in some cases cytochrome studies.

Moltano Institute A famous institute directed by David Keilin through the 1930–50s. It became a Mecca for those working with cell respiration.

Near-infrared (NIR) imaging The use of the wavelengths in the red region just at the verge of invisibility between 700 and 900 nm to better penetrate tissue.

Photochemical action spectrum The effect of light upon a biological system often used to activate a carbon monoxide-inhibited cytochrome.

Photomultiplier A highly sensitive light detector used in many spectrophotometers.

Photon migration The phenomenon of photon diffusion through tissues used in great detail recently to image subsurface objects.

Ruby laser One of the early forms of the laser, emitting in the red region.

Scattered light Light that does not proceed directly through tissue.

Spectrophotometer A device that measures the absorbance of materials as a function of wavelength or, in some cases, energy.

Time-resolved spectroscopy (TRS) Spectroscopy using sharp pulses of light to distinguish the scattering from the absorption of tissues.

X-ray absorption spectroscopy (EXAFS) Spectroscopy used to obtain high-resolution structures of Fe and Cu enzymes.

Manual Spectrometers

The rightfully famous physicist R.W. Wood made a high-quality plastic replica grating and incorporated a pair of them in the Coleman spectrophotometer to make a double-grating instrument that was valid from 400 to 700 nm, had a very good f number, and had a resolution independent of wavelength (~ 20 nm). This was an essential element of the kinetic and spectroscopic studies of the enzyme–substrate compounds of catalases and peroxidase, as carried out in the laboratory of Hugo Theorell. Although it was an excellent commercial instrument for laboratory work in a visible region, Cary's quartz monochromator, however, together with Beckman's unreferenced exploitation of DuBridge's ingenious electrometer (of the pH meter as well), made the Beckman DU instrument superior. However, if Charles Chaplin were to make a film of the biochemist similar to 'City Lights', this instrument would serve the purpose. Dark current adjustment, slit-adjustment, cuvette-holder shifting, and balancing to a null by hand were the earmarks of the instrument that most biochemists used from the 1940s to the early 1960s. Note that there were no alternatives. C.C. Yang invented what was called

the 'Yang machine', a very simple and robust instrument used by many in the Johnson Foundation laboratory, which used a vibrating mirror system to send light through a reference cuvette and a measure cuvette, together with dynode feedback, and gave a logarithmic output. Concurrently, Lenart Åckerman in the laboratory of Bo Thorell in Stockholm invented the same machine that also provided spectral scans but that was held off the market for about a decade, so the DU could have an orderly and prosperous senescence.

Dual-Wavelength Technology

The development of dual-wavelength systems began with Glen Millikan, who ingeniously scribed a barrier in the Weston photovoltaic cell and used green and red filters to measure myoglobin spectral changes in the visible region. However, he connected the output to a mirror galvanometer so that the system was intrinsically quite slow and, thus, unsuitable for the rapid measurements required for the flow apparatus. The dual-wavelength principle was continued in the Millikan ear oximeter used so effectively during World War II.

Rapid spectrophotometry required phototubes. The significant experience Britton Chance had acquired with them by inventing an automatic steering device while still in his teens led him to use cesium oxide on silver and then antimony as photocathodes. These were combined with the technology of high-gain direct current amplification from the electrophysiologists Adrian, Gasser, Erlanger, and the Schmitt brothers, who all had to develop an entire field of electronic amplification for studying nerve action potentials. The three-wavelength system used to measure the kinetics of enzyme–substrate compound formation in the Soret region, together with the overall formation of leucomalachite green to malachite green, provided measurements of enzyme–substrate compounds that required a mechanical differential analyzer for the transient solution of the Michaelis–Menten/Briggs–Haldane equations for enzyme kinetics (Figure 1). Indeed, the rapid flow apparatus led the field of fast spectrophotometric determinations, not only of the enzyme–substrate compounds of peroxidase but also, in the hands of Quentin Gibson, for measuring hemoglobin kinetics.

The introduction of the chopper-stabilized amplifiers in systems exploited during World War II by the Group 63 of

Chance and co-workers (Precision Circuits Group at MIT RadLabs) led to a whole new generation of low-level amplifiers and was the basis for many commercial instruments. Furthermore, the basis for the integrated circuit was afforded by the subminiature triodes developed for the proximity fuse, for which the rejection rate was so high that thousands of these diodes suitable for peacetime applications became available and were made in the first step of integrated circuits, precursors of the integrated chips that were soon to come in the postwar era.

Photochemical Action Spectra

One historic experiment, which now seems almost to have been forgotten, was performed by the Schmitt brothers in order to validate the Warburg hypothesis, namely, to obtain the photochemical action spectrum for the propagation of action potentials in nerves. The results did, in fact, coincide with Warburg's hypothesis and provided the much-needed link between prokaryote and eukaryote. The Schmidt brothers received very little credit for their work, without which Warburg's and Keilin's work, based on yeast cells only, would

These reactions are represented by Briggs and Haldane as the bimolecular combination of the enzyme, E , and substrate, S , to form an intermediate compound, ES , followed by a monomolecular decomposition into free enzyme and activated or altered substrate, Q , representative of the products of the 'over-all' enzyme action.

If e is the total molar enzyme concentration, x the molar substance concentration, p the molar concentration of ES , k_1 the second-order rate constant, and k_2 and k_3 the first-order rate constants, then

$$\frac{dp}{dt} = k_1 x(e - p) - (k_2 + k_3)p \quad (5)$$

$$\frac{dx}{dt} = -k_1 x(e - p) + k_2 p \quad (6)$$

These two equations represent the rate of formation of the intermediate compound and the rate of disappearance of the substrate.

The solution of these equations has been already obtained by Briggs and Haldane for the special conditions of the steady state, when

$$p = p_{\max}, \quad \frac{dp}{dt} = 0, \quad \text{and} \quad \frac{p_{\max}}{e} = \frac{x}{x - Km} \quad (7)$$

where

$$Km = \frac{k_2 + k_3}{k_1} = x \frac{(e - p_{\max})}{p_{\max}} \quad (8)$$

A further solution valid during the steady state is obtained by adding eqns 5 and 6,

$$\frac{dx}{dt} = -k_3 p_{\max} \quad (9)$$

where dx/dt is the rate of disappearance of substrate.

Figure 1 Michaelis–Menten theory.

Figure 2 Photochemical action spectrum of cytochrome oxidase as obtained by the LeRoy Castor using the oxygen electrode to measure light-activated respiration. It is seen that this spectrum is much better defined than Warburg's classic spectrum of yeast where mainly the lines of the mercury arc were employed. Here, a continuous monochromated light would be used and the σ bands were clearly delineated as are the Soret bands.

have been less acceptable (Figure 2). At the time, there was no reason to believe that the eukaryotic yeast cell was a model for tissue studies. LaRoy Castor quickly improved the action spectral method and also discovered a heme prosthetic group oxidase (cytochrome *o*).

Tissue Spectroscopy

Glen Millikan was a pioneer in shining light through tissue and recording myoglobin deoxygenation in functional activity. During the same time, there were many microspectroscopic studies by Arvanitaki and Chalazonitis, and also, notably, by the laboratory of Caspersen with his colleague Bo Thorell. Lundegårdh was a pioneer in applying the spectroscopic technique to bundles of plant roots, but was unable to correct for the large changes of scattering due to the osmotic activity of the roots. However, Lou Duysens developed a sensitive single-beam method that he applied with diligence and effectiveness to cytochrome components of green leaves.

A time multiplex dual-wavelength system made possible by simply mounting on top of the Brown converter, or vibrating a small mirror at 60 Hz, allowed time sharing of two wavelengths through suspensions of highly scattered material derived from heart muscle or from liver as intact mitochondria. This dual-wavelength machine was the precursor of the time multiplex systems that have been used for exploiting near-infrared (NIR) spectroscopy.

The Scattered Light Problem

It was recognized early on that the scattered light would confound spectrophotometric measurements of pigments of

Figure 3 The difference spectrum of intact phosphorylating mitochondria. This was the first difference spectrum for oxidized minus reduced guinea pig liver mitochondria obtained with the dual-wavelength method employing reference wavelengths of 540 nm for the alpha bands and 450 nm for the Soret bands. The incremental absorption with respect to that reference is indicated giving the ratio of the Soret to the alpha bands to be four and the NADH peak to be 40 times that of the alpha peaks. The flavoprotein trough, that is, oxidized flavoprotein is the absorber, is shown at 460 nm. Although the Soret peak of cytochrome oxidase was visible at 444 nm by Keilin's microspectroscope, the flavin trough and the NADH peak (the latter being responsible for the intense autofluorescence of cells) were not available to Keilin in Hartree's heart muscle preparation in which the absorbance of these two components was greatly diminished by the elimination of citric acid cycle enzymes.

tissue. Yet, in 1949, Chance recognized that the scattered light effect would be greatly diminished if the solid angle of the detector system was large instead of small, as in commercial spectrophotometers (for long cuvettes). Thus, instead of a 10-cm-long sample compartment, as used in most of the Beckman/Cary devices, Chance and co-workers placed a large area detector and an 'end-on' photomultiplier almost in contact with the sample, particularly using the time-shared dual-wavelength system, from which very flat baselines were obtained for spectroscopic differences as long as the wavelength difference was not too great. The difference spectrum obtained from guinea pig liver mitochondria is shown in Figure 3 as an example of the data that were obtained with the dual-wavelength spectrophotometer, where the baseline was set at the suspected isosbestic points of 540 and 630 nm. The action spectrum for reduction of the oxidized form of the electron carriers was measured. This spectrum, although validating Keilin's microspectroscopy, clearly showed some anomalies. Cytochrome c_1 was a separate component. A trough due to the disappearance of oxidized flavin and peaks due to appearance of reduced NADH were not identified by Keilin's keen eye, which proved to be the most useful components of the respiratory chain because they were highly fluorescent. But most importantly, they were inhabitants of the mitochondrial matrix space where most of the citric acid cycle reactions were carried out. The instrument was surely very worthwhile.

It had identified not only three components of the respiratory chain that had been previously underestimated or remained completely unobserved, but also, for example, the difference spectrum obtained by Lucille Smith and Aristid Lindenmeyer showed the P450 compound of carbon monoxide, an observation confirmed by G.R. Williams and used by P450 enthusiasts today.

Control of Respiration

No other phenomenon was as important to physiologists as the control of respiration. The topic had received very little attention until Lardy and Wellman's historic paper, which showed that isolated prepared mitochondria very nearly completely ceased respiration in the absence of adenosine diphosphate (ADP) and phosphate but restarted respiration upon addition of ADP and phosphate. This led Chance and Williams to explore the nature of activation of the electron carrier in the respiratory chain. They found that all spectroscopically identifiable components changed their steady-state values when ADP was added to the suspension of resting mitochondria. This phenomenon now provides the basis for all of the metabolic activations studied by magnetic resonance imaging (MRI) as the bulb effect, and for using the saturation of oxyhemoglobin (HbO_2) *in vivo* as a measure of metabolic activity.

At the same time, Lehninger, Chance, and others studied the uptake of calcium into the mitochondrial matrix, and Chance and Williams found that calcium activated the suspensions of mitochondria to the same extent and with the same speed as did ADP suggesting, as recently discussed by Carafoli, the presence of a calcium carrier in the mitochondrial membrane.

Low-Temperature Technology

Perhaps the most secure instrumental data were those obtained at low temperature in liquid nitrogen, where the spectra were more intense. The delineation of the absorption bands, particularly in the bc_1 region, turned out to be essential in showing the two kinds of cytochromes *b*.

Lubbers' Rapid Scan

Tissue absorption and scattering occupied the minds of a number of workers, particularly those of Lubber and Thews, who not only did much theoretical work on scattering but also perfected a galvanometer-driven wavelength scanning device, whose speed far exceeded that of anything else available at the time and which has only been perfected recently by the work of Desr and co-workers.

Photoactivation Studies

Perhaps the greatest advantage of the technique for observing tissue properties was the fact that it was possible to photoactivate the system under spectroscopic examination and observe the photoinduced absorption spectrum, a specialty of the Laboratory of Lou Duysems. This, of course, required a

measure of common mode rejection, at which the dual-wavelength system excelled because the light flashes shared a single detector with an alternating current coupling, allowing the system to reject leakage of not only the photolysis light but also other disturbances that affected the common mode. Furthermore, illumination at subzero temperatures of the solid phase allowed the study of many photoactivated systems containing derivatives of chlorophyll or those rendered photoactivatable by combining with a ligand such as carbon monoxide. Thus, optical measurements in the region of the Soret band and illumination in the region of the alpha band allowed a measure of protection of the dual-wavelength detector system from very strong photolysis light, for example, that provided by intense sources such as the carbon arc. These studies bridged the gap between Otto Warburg's unbridgeable action spectrum experiment on yeast and Keilin and Hartree's microspectroscopical observations of cytochrome oxidase in yeast and in a pigeon heart muscle preparation.

Not only the cytochrome oxidase-CO complex CO but also the splitting and recombination of myoglobin CO compounds were studied in detail, with optical spectroscopy as well as structural methods such as X-ray absorption spectroscopy, with results that make headlines even today for the subject of ligand-docking concomitant with structural changes, confirming the X-ray structural studies in which the E7 histidine was altered by a ligation of myoglobin with CO.

The Ruby Laser and Electron Tunneling

Lacking powerful light sources of short duration, Chance and co-workers relied mainly upon xenon flash lamps, particularly those of Edgerton and co-workers. However, construction of the first ruby laser used in biological studies by Bunkenberg and DeVault opened up a whole new time domain, not only because of the monochromaticity of the laser (which greatly simplified the filter leakages) but also because of the duration of the light pulse (in the microsecond region), which for the time was extraordinarily short. From this study came the totally unexpected observation that the photochemical oxidation of cytochrome *c* by photoactivated chlorophyll of *Chromatium* was temperature independent, not only from room temperature to liquid nitrogen temperature but also eventually at liquid helium temperatures, extending the time range of the spectroscopic method to one of the primary or near-primary results and/or reactions of photosynthesis (Figure 4), and also introducing the concept of electron tunneling in biochemical reactions, a concept pursued by Les Dutton and Harry Gray.

The history of spectroscopy is checkered with unexpected results and meaningful interpretations on the nature of electron transfer reactions. In fact, the study of reactions obtained from photolysis activation of CO compounds in the presence of O_2 caused ligand exchange to occur, especially in the case of CO. Together with Carlo Saronio, Chance discovered a number of intermediate steps involving higher oxidation states of iron mirroring those obtained with peroxidase and H_2O_2 , but much faster and more complex. This was because copper oxidation was involved in the active site of CO, enabling donation of four electrons sequentially for the reduction of oxygen to water without significant amounts of free radical intermediates.

Figure 4 Typical recording of the oxidation of cytochrome *c* of photosynthetic bacteria at low temperatures as activated by a light flash of the ruby laser. Remarkably, this reaction rate was affected very little by the transition from room temperature to liquid nitrogen temperature due to electron tunneling.

This contrasted with the photoactivation of porphyrins in the absence of electron donors, resulting in the creation of singlet oxygen, a process used extensively in photodynamic therapies.

Fluorochromes of Tissues

Spectroscopy of biological fluorochromes, such as NADH and flavoprotein compounds that exhibit strong fluorescence in mitochondria, led Chance and co-workers to study them extensively *in vivo* by a simple method in which excitation was obtained by the very strong 366 and 436 lines of the mercury arc. This yielded emission spectra characteristic of the chromophores in a variety of functional states, characterizing electron transfer through the citric acid cycle as reductant and the cytochrome chain as oxidants, giving essential features of the redox state of the mitochondrial matrix. Interpretations of the importance of metabolic control and thermodynamic principles of the system were derived from these, particularly by R.L. Veech.

Hemoglobin and Cytochrome

It is perhaps ironic that the cell biologists and etymologists of the Molteno Institute focused on the cytochromes of hemoglobin-free cells and tissues and that the real physiology of oxygen delivery to tissues by hemoglobin and its utilization by CO had to wait for more sophisticated methods. Even now, the observation of cytochrome oxidase absorption bands in the presence of physiological concentrations of oxy- and deoxyhemoglobin is fraught with controversy, to the point that no reliable spectroscopic distinction of the copper component of cytochrome oxidase and the overlapping spectra of HbO₂ has been obtained. In fact, nearly all studies find that the so-called cytochrome oxidase Cu changes track those of HbO₂ due to the similarity of their spectroscopic absorption bands in the NIR region, and the great predominance of hemoglobin absorption over that of cytochrome oxidase.

NADH as an Oximeter

It has been shown that the fluorescence of NADH and flavoprotein, when used in a ratiometric manner, can exhibit a

reasonable immunity to changes of hemoglobin concentration, and has afforded standards for the independent changes of hemoglobin and NADH in transient hypoxia and reoxidation. Such independence of the measures of cytochrome and hemoglobin has never been clearly demonstrated for the copper component of cytochrome oxidase, due to the overlapping spectra of HbO₂.

An alternate approach was based upon the fluorescence of the newly discovered NADH and flavoprotein components of the mitochondrial respiratory chain, particularly by using the ratio of these two fluorochromes. Fortunately, NADH fluoresced in the reduced state, while flavoprotein fluoresced in the oxidized state, so their ratio was a measure of the redox state of mitochondria, a signal that was found to be only marginally affected by changes in the oxygenation of hemoglobin in model systems. Using this criterion on the very strong signal of NADH only, it was possible to show that the fluorescence of NADH was unchanged until the oxy/deoxy transition of hemoglobin was almost complete in a system in which functional activity was measured by the photoaction potential of an animal model, removing any doubt about the higher oxygen affinity of cytochrome *in vivo* as compared to hemoglobin (~20 torr). This was a very important milestone for physiologists, who know that the deoxygenation of hemoglobin is very high and the critical *p*O₂ of mitochondrial function is compromised. Thus, the calibration of tissue oximeters in the region of intravenous saturation of hemoglobin (i.e., 20–30%) must be precisely measured to indicate critical tissue hypoxia *in vivo*. This indeed was subsequently validated by measurements of tissue energetics through phosphorus nuclear magnetic resonance (³¹P NMR), particularly by measurements of the phosphocreatine:phosphate ratio.

NIR Spectroscopy

Jobsis used Kramer's technique to measure in the infrared, and developed a technology for the measurement of absorption of the copper component of cytochrome oxidase in the region of 830 nm based upon studies of the cat model and the heads of neonates, which he termed 'transcranial spectroscopy'. He further developed algorithms based upon fluorocarbon-perfused cat brain to give optical pathlengths that were believed to be transferable to the neonate brain and allow a deconvolution of blood volume and saturation changes from those of cytochrome oxidase signals using the full-length light algorithm. Delpy and co-workers avidly followed the lead of Jobsis and developed a close correlation between the decreased concentration of HbO₂ and the so-called copper signal in a number of models, suggesting that the mitochondria in tissues contained a low-affinity cytochrome oxidase and responded to *p*O₂ (in a slice) in a way similar to that of hemoglobin. However, isolation of rat brain mitochondria failed to support this contention. Furthermore, the freeze-trapped hypoxic brain failed to show the absorption band of reduced cytochrome *c* in mild hypoxic stress that caused deoxygenated hemoglobin. In fact, the absorption band of reduced cytochrome *c* was not observed until the band of HbO₂ was no longer detectable, according to the work of Bashford.

Although attempts were made to detect the copper absorption band of hemoglobin in the NIR region, animal studies showed that the fluorescence of NADH and the flavoprotein could be used to detect anoxia in the presence of hemoglobin, particularly when the ratio of the fluorescent-oxidized flavoprotein and the fluorescent-reduced NADH were employed; this value was relatively insensitive to the hemoglobin concentration. In fact, further demonstrations showed that the fluorescence of NADH was unaffected by the deoxygenation of hemoglobin in animal model brain. The NADH fluorescence increased in hypoxia only when the hemoglobin was already almost completely deoxygenated. This observation suggests that measurements of the critical pO_2 in hypoxia require accurate measurement of extreme values of hemoglobin desaturation, at the critical pO_2 for mitochondrial function.

NIR Spectroscopy of Brain and the BOLD Effect Measured by MRI

Much interest in the NIR method is based upon Ogawa's finding that changes in deoxyhemoglobin concentration (changes of the paramagnetic species of deoxyhemoglobin) enhanced water relaxation in the brain. This opened up the field of study of the activation phenomenon in the human brain, in which changes in deoxyhemoglobin levels are measured by NMR and by NIR tissue spectroscopy. The MRI changes are precisely imaged, while the NIR images, although crude, are measures of the rapidity of the changes. But in addition to incremental changes of deoxyhemoglobin, NIR could measure the saturation value of

hemoglobin, which, for reasons involving Beer's law, originates mainly from the arteriolar/capillary/venolar bed. This feature, namely, the value of local oxygen extraction due to incremental changes of mitochondrial functional activity (i.e., localized activation), is not measured by MRI. The two techniques are now widely accepted as indicative of localized brain activation and have afforded the basis for in-depth studies of visual and sensory motor function. But, most importantly, NIR gives an excellent rendition of prefrontal cortex signals without the difficulty of the large water content of the ocular system encountered with NMR (Figure 5). The use of activation images is appropriate to the NIR system, where baseline values may be somewhat variable and difficult to calibrate. The incremental changes of blood volume measured as changes of total hemoglobin, together with the aforementioned oxygen-extraction measure, that is, desaturation of hemoglobin, can be directly related to local metabolic activity, opening up a new field of NIR study of the semi-quantitative nature of the hemoglobin signals.

NIR Imaging

Although the above-mentioned studies used dual-wavelength technology stemming from that of Glenn Millikan, a completely new concept was introduced by the discovery that photon migration through tissues can be modeled by the diffusion equation. Multiple sources and detectors give very reasonable two- and three-dimensional imaging, and the propagation of light through tissue can be quantified by pulse time and phase and amplitude measurements, much as has been the case with measurement of fluorescence.

Figure 5 Evidence of activation of metabolism measured in the near-infrared (NIR) by the dual-wavelength method of 760–850 nm (equibestic wavelengths), which show progressive deoxygenation of the quadriceps muscle of a trained athlete during bicycle exercise up to the remarkable level 500 W, at which nearly complete deoxygenation of hemoglobin can occur as measured separately by the sum of signals at these two wavelengths. With appropriate coefficient, the increase of blood flow in the muscle also occurs giving a larger absorbance signal. At this level of exercise, it is probable that myoglobin is not deoxygenated as indicated by separate experiments with animal models.

Photon Migration in Tissues

The discovery that photons migrating through tissue followed the diffusion equation and that the tracks could be simulated by Monte Carlo methods, together with the adaptation of time-correlated single photon counting to the task of measuring propagation times in tissues, opened up an entire field of NIR spectroscopy and imaging. This grew to be a field of medical science in a manner similar to NMR, but differing in the fact that the necessary equipment is not nearly as expensive, so the proliferation of the technique in research laboratories could be much more rapid. Because the profit margins did not match those of NMR, commercial production of NIR imagers has been restricted to two or three companies.

Tissue Optical Properties

Three techniques are outstanding in the measurement of tissue optical properties. The first, and still the foremost, is the pulse time method, in which photon delay is caused by scattering and photon attenuation is caused by absorbers such as hemoglobin, water, and lipid. Because time-resolved spectroscopy (TRS) immediately deconvolutes scattering and absorption by time domain analysis, it is a preferred method. Similarly, variable frequency-modulated light will unravel by Fourier transformation exactly the same quantities as those obtained by TRS. However, the difficulty of stabilizing the phase shifts of electronic systems of variable frequency, together with the limitations of detection response to high-frequency radio waves, has limited this system to approximately 400 MHz. Nevertheless, many instruments have been made in the frequency range of 50–200 MHz that are used for quantifying absorption and scattering in multiwavelength systems and that are capable of measuring hemoglobin saturation with significant precision. Such systems have adopted some cell phone components and are therefore compact and cheap.

The most reliable and most used system modulates the light at very low frequencies in either, or time shares the light sources in a multiplex system, and appears to be the preferred system for many applications. The deconvolution of scattering and absorption can be obtained if sufficient data are taken at various source–detector separations and optical wavelengths to include the scattering variations.

Cancer Detection

In cancer detection, scanning the breast, for example, an activation signal based upon angiogenesis and hypermetabolism is given, causing more blood volume and more deoxygenated hemoglobin to be present. Although this criterion may not be applicable to all cancers, it has given remarkably good scores in one breast cancer study.

Muscle Studies

A series of studies has been based upon activation measurements, in which (e.g., in both muscle and brain) functional activation causes hemodynamic changes due to mobilization of blood flow and saturation changes due to varying metabolic activity (Figure 5). This has been used in muscle not only to evaluate exercise capability, but also to quantify disability due to occlusive disease in the limbs.

Brain Functional Activation

In brain studies, whereas NMR and the optical method both measure hemodynamic activation due to functional activity, the NIR method is unique in that it measures changes of hemoglobin saturation caused by varying degrees of oxygen

Figure 6 Illustrating the use of the NIR continuous wave dual-wavelength system in localizing the particular voxels in the human forebrain at which brain functional activity is indicated to be increased by the oxygenation changes with respect to the baseline level of 3 letter anagrams. Each colored symbol represents the average of over 100 tests of a particular individual giving an average value of 8 μM oxygenation under this condition of maximal stress. The region observed is the Broadman's 9 and 10 or ear-to-ear and hairline-to-eyebrow region of the projection of the prefrontal cortex. This separation was 4 cm in order to ensure signaling from the prefrontal cortex to accentuate the absorbance changes due to the prefrontal cortex and minimize those that might be associated with tissue layers at smaller depths.

extraction from the capillary blood vessels of the brain. Thus, the convenience and economy of the optical method lends itself to studies of minimally perturbed human subjects, be they adults or neonates (Figure 6).

Brain Studies: The Neuronal Signal

The early studies of David Hill, Tasaki, and Richard Keynes on transparency changes of axons upon stimulation suggest that a functional optical signal could be obtained in animal and human brain. Although the studies of Salzberg did indeed verify the scattering changes in isolated preparations, studies using NIR to seek similar changes in the human brain suggest that only very small and somewhat irreproducible signals can be obtained. For example, the early experiments of Gabriele Gratton have not been duplicated either by himself or by others working in the field (Villringer and Franceschini, and Wolf), in part, due to instrumental difficulties, and in part due to the very small size of the signal. The rise time of the signals appears to be in the range of 100 ms and the amplitude as small as one part in 10^4 or even smaller. However, the relatively robust signals obtained from the hemodynamic and metabolic activations discussed previously show the feasibility of measurements of functional activity in the human brain, particularly in the prefrontal region, and open up a reliable and economical method for human brain studies that predict a vibrant future of the optical methods in human studies.

Summary

The story of the development of optics in biochemistry and biophysics does not end here. In fact, some might say that this is just the beginning of the transferability of optical tomography and optical biopsy to small animals on the one hand and human beings on the other. Perhaps spurred by the interest in online methods for evaluating the growth and recession of cancers under the influence of appropriate drugs in small animals, transferability of these principles to human subjects is becoming important. The optical method is taking its place along with MRI, positron emission tomography, ultrasound, computed tomography, and X-ray mammography as methods for studying pathologies in the human body.

Sphingolipid Biosynthesis

A H Merrill Jr., Georgia Institute of Technology, Atlanta, GA, USA

© 2013 Elsevier Inc. All rights reserved.

Glossary

Ceramide An N-acyl-derivative of sphingosine that is both a metabolic intermediate and a cell-signaling molecule. In some cases, the term is applied generically to any N-acyl-sphingoid base.

Glycosphingolipid A compound with a carbohydrate bound to a sphingoid base (and most often, attached to position 1 of an N-acyl-sphingoid base).

Glycosyltransferase An enzyme that transfers a carbohydrate from a donor (usually a UDP-sugar) to an acceptor which, in the case of sphingolipids, is either a ceramide or a carbohydrate chain attached to ceramide.

Mass spectrometry An instrument that separates ionized molecules by their mass to charge ratio (m/z) to allow them to be structurally characterized and quantified, with appropriate internal standards.

Phosphosphingolipid A compound with a phosphate or phosphodiester linked headgroup attached to a sphingoid base (or more often, to position 1 of an N-acyl-sphingoid base).

Sphingoid base The backbone of more complex sphingolipids as well as a cell-signaling molecule. Structurally, a long-chain alkane (or alkene) with an amino at position 2, and (usually) hydroxyl groups at position 1 and 3 plus various alkyl chain lengths, degrees of unsaturation, and additional hydroxyl groups.

Sphingolipidomics The analysis of all of the sphingolipids in a biological system (the sphingolipidome or a logically selected subset that includes all of the subspecies of interest for a particular biological system or phenomenon).

Sphingosine 1-phosphate A bioactive metabolite that serves as an intracellular and an extracellular signal as well as an intermediate of sphingoid base catabolism.

Introduction

Sphingolipids are a complex family of compounds produced by eukaryotes and some prokaryotes and viruses to play structural roles, such as formation of membrane bilayers and rafts, stabilization of lipoproteins, and maintenance of the water barrier of skin, and to serve as intra- and extra-cellular signaling molecules. They share a common structural feature, a so-called sphingoid base backbone that is comprised of an alkyl chain of approximately 18 carbon atoms with one to three hydroxyl groups and one amino group at position 2 (or in one case, at position 1) of the alkyl chain. Sphingoid bases are made *de novo* by mammals and converted into more complex sphingolipids (sphingoid base 1-phosphates, ceramides, phosphosphingolipids, glycosphingolipids and protein adducts). Several diseases result from genetic defects in *de novo* sphingolipid biosynthesis or disruption of the pathway by environmental factors, and many diseases are characterized by abnormal sphingolipid amounts and/or compositions. Therefore, sphingolipid biosynthesis is being explored for its possible role in the etiology of many diseases, such as cancer, and possibly as new targets for drugs and other interventions.

Structures and Nomenclature

Sphingolipids can be divided into several major categories: the sphingoid bases and their simple derivatives, ceramides, and more complex sphingolipids as summarized in Figures 1 and 2.

Sphingoid Bases

The most fundamental feature of these compounds was named sphingosine by J. L. W. Thudichum when he reported its discovery (in 1884) "in commemoration of the many enigmas which it presented to the inquirer." The structure of sphingosine, the major sphingoid base of mammals, is (2*S*,3*R*,4*E*)-2-aminooctadec-4-ene-1,3-diol (it is also called 'D-erythro-sphingosine' and 'E-sphing-4-enine') (Figure 1). The other sphingoid bases found in mammals vary in alkyl chain length and branching, the number and positions of double bonds, the presence of additional hydroxyl groups, and a few other features. Mammals have also been discovered recently to have atypical sphingoid bases that lack the 1-hydroxyl group, as shown for 1-deoxysphinganine in Figure 1.

Sphingoid bases function as intra- and extra-cellular signals and second messengers in the form of free sphingoid bases and derivatives (sphingoid base 1-phosphates and ceramides, and possibly other species) (Figure 1). Free (underivatized) sphingoid bases are usually present in cells in relatively small amounts versus more complex sphingolipids.

Ceramides

Ceramides are fatty acid derivatives of sphingoid bases (Figure 1). The fatty acids are typically saturated or mono-unsaturated with chain lengths from 14 to 26 carbon atoms (or even longer in the special case of skin), and sometimes

Figure 1 Structures of representative sphingolipids. Shown are several examples of sphingoid bases (sphingosine, sphinganine and 4-hydroxysphinganine, as well as an atypical sphingoid base, 1-deoxysphinganine), a ceramide (N-acyl-sphingosine), and headgroup phosphosphingolipids, such as sphingomyelin (SM), and glycosphingolipids, which are shown in more detail in **Figures 2** and **4**.

have a hydroxyl group on the α - or ω -carbon atom. These structural features favor the segregation of ceramides and some complex sphingolipids into specialized regions of the membrane (called rafts and caveolae) that participate in cell signaling, nutrient transport, and other functions.

Ceramides also serve as second messengers that modulate the biophysical properties of membranes, activate and inhibit proteins that participate in cell signaling (e.g., protein kinases and phosphoprotein phosphatases) and control cell growth, senescence, and programmed cell death (apoptosis). Their biologic activity depends on the type of sphingoid base and fatty acid; for examples, dihydroceramides (i.e., without the 4,5-double bond of the sphingosine backbone) (**Figure 1**) are less potent than ceramides as inducers of apoptosis, but are able to induce the formation of large intracellular vacuoles called autophagosomes.

More Complex Phospho- and Glyco-Sphingolipids

The major phosphosphingolipids of mammals are sphingomyelins (**Figure 2**), followed by much smaller amounts of ceramide 1-phosphate, which participates in cell signaling, and trace levels of ceramide phosphoethanolamines. Glycosphingolipids are classified on the basis of carbohydrate composition. One way to categorize them is by charge: neutral glycosphingolipids contain one or more uncharged sugars such as glucose (abbreviated Glc, hence, glucosylceramide is GlcCer), galactose (Gal), N-acetylglucosamine (GlcNAc), N-acetylgalactosamine (GalNAc), and fucose (Fuc); whereas, acidic glycosphingolipids contain phosphate or sulfate (the latter being called sulfatides) attached to neutral sugars, or charged sugar residues such as glucuronic acid or sialic acid (which is actually a general name for a family of compounds, for the type in human sphingolipids

is N-acetylneuraminic acid, Neu5Ac) (**Figure 2**). Gangliosides, such as those shown in the figure, are a subcategory of glycosphingolipids with sialic acid, and the number of sialic acid residues is usually denoted with a subscript letter (i.e., mono-, di- or tri-) plus a number (and sometimes additional symbols) reflecting the subspecies within that category, as shown for gangliosides GM1a, GM2, and GM3.

Another nomenclature system, which is becoming more common, is to categorize the glycans by a so-called root structure, as shown in **Figure 2** for the tetrahexose backbone of GM1a (Gal β 1-3GalNAc β 1-4Gal β 1-4Glc β 1Cer). This is called the ganglio- root structure (which is a bit confusing with the term gangliosides referring to sialic acid containing glycosphingolipids). The other root structures for mammalian glycosphingolipids are: lacto- (Lc), Gal β 1-3GlcNAc β 1-3Gal β 1-4Glc β 1-1'Cer; neo-lacto (nLc), Gal β 1-4GlcNAc β 1-3Gal β 1-4Glc β 1-1'Cer; globo (Gb), GalNAc β 1-3Gal α 1-4Gal β 1-4Glc β 1-1'Cer; and isoglobo (iGb), GalNAc β 1-3Gal α 1-3Gal β 1-4Glc β 1-1'Cer; and root structures found in other organisms, such as insects, are mollu (Mu), GalNAc β 1-2Man α 1-3Man β 1-4Glc β 1-1'Cer and arthro (At), GalNAc β 1-4GlcNAc β 1-3Man β 1-4Glc β 1-1'Cer. By this system, the structure is described by the root name plus any substituents, with designation of where they are added by a Roman numeral with a subscript for the hydroxyl to which it is attached (II³ in **Figure 2** for the position of attachment of the Neu5Ac in ganglioside GM1a).

A few glycosphingolipids are still referred to by historically assigned names, such as the blood group antigens (e.g., Lewis x and sialyl-Lewis x). Because these terminologies – and the structures themselves – can be confusing, there is growing usage of symbols to display the glycans, and a generally well-followed convention to depict them is shown in **Figure 2** (e.g., glucose as a light blue circle, glucosamine as a square with the same color, etc.).

Figure 2 Structure of representative glycosphingolipids. The chemical structure shown is for ganglioside GM1a, but the structure also displays its component parts that represent a monohexosylceramide (glucosylceramide, Glc), a dihexosylceramide (lactosylceramide), and other subcategories of gangliosides (GM3 and GM2), with alternative ways of depicting such compounds (i.e., by explicit structures or symbols for the carbohydrates).

Protein Adducts

Some sphingolipids are covalently attached to protein, for example, ω -hydroxy-ceramides and -glucosylceramides are attached to surface proteins of skin; and, inositol-phosphoceramides are used as membrane anchors for some fungal proteins, in a manner somewhat analogous to the glycosylphosphatidylinositol (GPI)-anchors that are attached to proteins in other eukaryotes.

De novo Biosynthesis of Sphingolipids

Sphingolipid biosynthesis is widespread among eukaryotic cells, a few bacteria, and one recently discovered algal virus, and it appears that new synthesis (i.e., *de novo*) is relied upon more than reutilization of sphingolipids from exogenous sources, such as food. The biosynthetic pathway for such a diverse family of compounds (conservatively estimated to be in the tens of thousands) is obviously complex, however, its fundamental features are summarized in [Figure 3](#) with the steps in the biosynthesis of the lipid backbone at the top one-third of the scheme and most of the early steps in headgroup addition in the lower two-thirds.

Biosynthesis of the Lipid Backbone

The initial step of the pathway is catalyzed by serine palmitoyltransferase (SPT), a pyridoxal 5'-phosphate-dependent heterodimer (of SPTLC1 and SPTLC2, and perhaps additional proteins) that condenses serine and palmitoyl-CoA to

form a 3-keto-intermediate that is rapidly converted to sphinganine by an NAD(P)H-dependent reductase ([Figure 1](#)). The palmitoyl-CoA selectivity of this enzyme is a major determinant of the 18-carbon chain length of the majority of mammalian sphingoid bases, and recent studies indicate that additional SPT isozymes and/or associated proteins can shift the fatty acyl-CoA selectivity to produce other types (for example, elevation of SPTLC3 increases the production of d16:0 sphingoid bases).

SPT has been recently discovered to utilize alanine to produce 1-deoxysphinganine (m18:0) ([Figure 1](#)) and glycine to make 1-(deoxymethyl)sphinganine (m17:0). These atypical sphingoid bases are found *in vivo* and are probably not mistakes, but additional subcategories of sphingolipids with their own biochemical functions. Moreover, there is growing evidence that the neuronal damage in human hereditary sensory neuropathy type I (HSN1), the most common hereditary disorder of peripheral sensory neurons, is due at least in part to an abnormal elevation in 1-deoxysphingoid bases due to mutations in SPT.

Sphinganine is next N-acylated by ceramide synthases (CerS) to produce dihydroceramides using, mostly, the fatty acyl-CoA's shown in [Figure 3](#). The proteins produced from the six known CerS genes vary in fatty acyl-CoA selectivity to allow specification of the chain-length distribution bases on the relative expression levels and the available fatty acyl-CoA's. CerS1 is highly specific for C18:0; CerS2 for very-long-chain fatty acyl-CoA's (ca C22 to C26); CerS3 appears to produce the very-long-chain Cer found in skin ($\geq$ C26); CerS4 utilizes fatty acyl-CoA's with $C20 \pm 2$; CerS5 is fairly specific for C16- and CerS6 utilizes C14- and C16-fatty acyl-CoA. The nature of the ceramide subspecies affects not only the biophysical properties of cell membranes, but also can profoundly alter cell behavior,

Figure 3 The *de novo* biosynthetic pathway for sphingoid bases and ceramides. Starting with serine palmitoyltransferase (SPT), the upper third of the figure depicts the biosynthesis of sphinganine, which can be phosphorylated by sphingosine kinase (SphK) or N-acylated by ceramide synthases (CerS) to dihydroceramides (d18:0; Cx,y) with the different acyl chains shown by chain length and number of double bonds (Cx,y). Ceramides (d18:1; Cx,y) are made by the dihydroceramide desaturases. Addition of the headgroups is shown in [Figure 4](#).

as exemplified by the finding that CerS1 and C18-ceramides are low in head and neck cancer, and their restoration partially normalizes the behavior of these cells in culture. Sphinganine can also be phosphorylated by sphingosine kinase (SphK) and, to some extent, acylation and phosphorylation are competitive because CerS and SphK reside in the endoplasmic reticulum.

Insertion of double bond(s) into the sphingoid base backbones occurs mainly after formation of dihydroceramide(s) ([Figure 3](#)). For mammals, introduction of the 4,5-double bond is catalyzed by a pyridine nucleotide-dependent desaturase, DES1; and possibly also by DES2, which is mainly responsible for addition of the 4-hydroxyl-group of phytoceramides.

The *de novo* biosynthetic pathway for ceramide is activated by a large number of factors, including bacterial endotoxins, cytokines, cancer chemotherapeutic drugs, and irradiation, and the increased production of ceramide is thought to be responsible for the toxicity of some of these treatments. Ceramide elevation was once thought to be the mechanism for the toxicity for the anti-cancer drug fenretinide (4-hydroxyphenylretinamide); however, later studies established that fenretinide inhibits DES and dihydroceramides are actually elevated, which induces autophagy.

Two useful reagents for studies of *de novo* sphingolipid biosynthesis are myriocin (ISP1), which is a potent inhibitor of SPT, and fumonisins, which inhibit CerS. Ceramide synthase inhibition appears to be the mechanism for the toxicity and carcinogenicity of fumonisins, which are mycotoxins produced by fungi that grow on corn.

Headgroup Addition for Formation of More Complex Sphingolipids

Ceramides in their various forms (i.e., ceramides, dihydroceramides, phytoceramides, etc.) are at a key branchpoint of complex sphingolipid biosynthesis where these intermediates are partitioned into phosphosphingolipids and glycosphingolipids, as shown in the lower portion of [Figure 4](#). The fate of a given intermediate is governed by the relative activities and selectivity of the enzymes at this branchpoint as well as by the subcellular localization of the participants.

Sphingomyelin and other phosphosphingolipids. Sphingomyelins are synthesized by at least two sphingomyelin synthases (SMSs) that transfer phosphorylcholine from phosphatidylcholine to ceramides in the endoplasmic reticulum, Golgi, and plasma membranes. This reversible reaction links glycerolipid and sphingolipid metabolism and signaling because ceramides and diacylglycerols both function as metabolic intermediates and as intracellular second messengers. This may explain why cells produce dihydroceramides as the initial products of *de novo* sphingolipid biosynthesis since that allows a relatively innocuous intermediate to accumulate if later steps in the pathway slow (although, as noted above, dihydroceramides are not inert because their elevation induces autophagy). A structurally related, endoplasmic reticulum enzyme is responsible for making ceramide phosphoethanolamines. Ceramide phosphate is made by phosphorylation of ceramide by ceramide kinase (CERK), which is found in the Golgi.

The transport of ceramide from its site of *de novo* biosynthesis (the endoplasmic reticulum) to the Golgi and plasma membrane is effected through both vesicular trafficking and the ceramide transport protein CERT. Because CERT prefers ceramides with ~C16 fatty acid chain length, downstream enzymes that utilize the ceramide that it has delivered are often enriched in that chain length. CERT is identical to a splicing variant of Goodpasture antigen-binding protein (GPBP), which plays a role in Goodpasture disease, an autoimmune disorder.

Glycosphingolipids. The addition of the carbohydrate headgroups is catalyzed by glycosyltransferases that transfer a specific sugar from the appropriate sugar nucleotide (UDP-Glc, UDP-Gal, CMP-sialic acid, etc.) to ceramide or the nonreducing end of the growing carbohydrate chain attached to ceramide. These enzymes are usually specific for the transferred carbohydrate, the carbohydrate (the type of transfer it will catalyze – i.e., α - or β - and to which particular hydroxyl-group on the glycan) and the general class of acceptor, although in some cases, the glycosyltransferases can add to both glycosphingolipids and glycoprotein chains. The abbreviations for the enzyme names in [Figure 4](#) provide information about the reaction they catalyze; for example: β 3GlcNAcT is a glycosyltransferase that transfers N-acetylglucosamine (GlcNAc) to the 3 position of the acceptor carbohydrate in a beta (β) linkage (a carbohydrate numbering scheme and β -linkage is shown for the glucose of ganglioside GM1a in [Figure 4](#)).

Figure 4 The biosynthetic pathway for complex sphingolipids. The key for this figure is the same as for Figures 1 and 2. Starting with a ceramide backbone (the octagon labeled “d18:1; cx:y”, as an example), the figure shows how ceramides are converted into sphingomyelins (SM) by SM synthases (SMS), phosphorylated to ceramide 1-phosphate (CerP) by ceramide kinase (CERK), or glycosylated to glucosylceramides (GlcCer) or galactosylceramides (GalCer) by the shown synthases. The other abbreviations are standard for the enzyme reactions shown, such as β 4-GalT, for the glycosyltransferase that transfers galactose (Gal) to the 4 position of the acceptor carbohydrate (GlcCer) in a beta (β) linkage. The enzymes that add sialic acid (Neu5Ac) are ST3Gal and SAT IV. Note the manner in which a single enzyme (such as β 4GalNAcT) can act on more than one substrate to make multiple downstream products in a ‘combinatorial’ manner, as depicted in the biosynthetic pathways for gangliosides GM1a and GM1b.

GlcCer and GalCer are the simplest glycosphingolipids, and are synthesized by UDP-Glc (or Gal): ceramide glycosyltransferases (coded for by the *Ugcg* and *Ugt8* genes, respectively). Hence, one determinant of the types of glycosphingolipids made by a given cell type is whether it expresses one or both of these genes. This branchpoint is also regulated by the availability of ceramide because GalCer is made in the lumen of the endoplasmic reticulum whereas GlcCer biosynthesis occurs on the side facing the cytoplasm (where enzymes for *de novo* ceramide biosynthesis are located) and/or Golgi. Therefore, even if the synthase for GalCer is expressed, the rate of synthesis of gala-family glycosphingolipids will depend on whether substantial amounts of ceramide flip from the outer to inner leaflet of the endoplasmic reticulum. Likewise, sulfatide biosynthesis is catalyzed by sulfotransferases inside the endoplasmic reticulum/Golgi and the nature of the products will depend on the type of sulfotransferases expressed (i.e., for 3'- or 5'-sulfo-) and the availability of the substrates (GalCer or other glycosphingolipids as shown in Figure 4) and the activated sulfate donor 3'-phosphoadenosine-5'-phosphosulfate.

The major fate of GlcCer is to traverse the Golgi membrane and be glycosylated to lactosylceramide (LacCer, Gal β 1-4Glc β 1Cer) in the lumen using UDP-Gal. LacCer synthase is thought to be encoded by some of the six members of the β -1,4-galactosyltransferase (β 4GalT) gene family, with β 4GalT-5 having been shown to be essential during early mouse embryogenesis. At this point, LacCer branches toward the root structure families of

glycosphingolipids, as shown in Figure 4, via the stepwise transfer of neutral sugars and sialic acid(s). These branches generally occur in different subcompartments within the Golgi. For example, the sialyltransferase catalyzing the synthesis of a simple ganglioside (ganglioside G_{M3}) is in the *cis* Golgi, whereas enzymes involved in terminal steps of more complex gangliosides are located in the more distal *trans* Golgi network.

Regulation of complex glycosphingolipid biosynthesis involves both transcriptional and posttranscriptional factors. For example, developmentally regulated, tissue selective variations in ganglioside amounts and types in mammalian tissues are under transcriptional control, but the activities of glycosyltransferases can be fine-tuned by posttranslational modification.

Other Metabolic Processes

In recent years, it has become evident that biosynthesis of sphingolipids for a particular cellular function also occurs outside of the endoplasmic reticulum/Golgi network. Some of these involve turnover of more complex sphingolipids with recycling of component part(s). One example of this is the hydrolysis of sphingomyelin to produce ceramide, which is subsequently phosphorylated to ceramide 1-phosphate. Cells also contain metabolites such as sphingosine 1-phosphocholine (lysosphingomyelin) that are involved in cell signaling, but for which a biosynthetic (or catabolic) pathway has not yet been discovered.

Modification of glycosphingolipids occurs at numerous sites, including the nucleus, mitochondria, and plasma membrane, presumably for the purpose of membrane remodeling or signaling. This includes removal of sialic acid(s) from gangliosides by a plasma membrane-associated sialidase (termed 'Neu3') and addition of sialic acid by at least one sialyltransferase (Sial-T2, or GD3 synthase), which has not only been noted at the cell surface, but also appears to exist as an ecto enzyme – that is, on the outer leaflet of the plasma membrane – using CMP-NeuAc available in the extracellular milieu.

This article has not discussed the classic lysosomal turnover of sphingolipids and the associated diseases from genetic defects in many of the steps of these pathways (e.g., Niemann-Pick, Gaucher and Sandhoff's disease, to name just a few). Interesting, some of the enzymes that were formerly thought to be dedicated to sphingolipid catabolism, such as the acidic sphingomyelinase, are now known to have functions in cell signaling and membrane repair. Therefore, they too should be borne in mind in thinking about the metabolic events taking place in the cell.

Sphingolipidomics

The large number and structural complexity of sphingolipids make quantitative analysis of all of the molecular subspecies technically impossible, and analysis of even a modest subset – such as all the ceramides – is difficult if the samples are small, such as cells in culture. However, large numbers of compounds can be analyzed by a combination of gas, liquid, or thin-layer chromatography with tandem mass spectrometry using electrospray or matrix-assisted laser-desorption ionization (MALDI) to convert the compounds of interest into ions that can be analyzed with a substantial degree of structural specificity by tandem mass spectrometry using quadrupole, time-of-flight, ion traps, or Fourier transform ion cyclotron resonance instruments. One of the major barriers to quantitative analysis is the lack of internal standards; however, this is being addressed by the LIPID MAPS Consortium (www.lipidmaps.org) in collaboration with Avanti Polar Lipids. Mass spectrometry can also be used to gain more information about sphingolipid biosynthesis and turnover by using stable isotope precursors, such as [^{13}C]palmitic acid, to label the sphingoid base backbone and N-acyl chains.

One of the most recent developments in sphingolipidomic mass spectrometry is the analysis of sphingolipids in tissue slices, which allows the location to be matched with what is known about the sample from more traditional histological staining. Examples of the application of tissue imaging mass spectrometry (also called MALDI-imaging mass spectrometry when that is the mode of ionization) include determination of the distribution of different gangliosides in specific regions of the brain, and localization of sulfatides in ovarian cancer cells versus stroma in biopsy samples. Although the resolution of tissue imaging mass spectrometry is currently at the histologic level (tens of microns), methods are under development that are using other means of generating ions to achieve sub-micron resolution, which will be of great value in basic and translational studies of these compounds.

Perspectives

For over a century, field of sphingolipidology has mystified scientists with its novelty and complexity, but in large part, what kept it mysterious was the lack of sufficiently sophisticated tools to study their structures, metabolism, and functions. This has changed radically in the last decade with the availability of mass spectrometry, immunohistochemistry, and other analytical tools, and identification of many of the genes for sphingolipid biosynthesis and turnover, allowing creation of cells and knockout mice to probe the functions of specific compounds. All of this new information is daunting in-and-of-itself; however, biosciences in general have recognized that they can only be fully understood by systems analysis – that is, how the multiple components of a living organism fit together, including the sphingolipids.

Glossary

Cerebroside A glycosphingolipid containing a single carbohydrate, most commonly glucosylceramide and galactosylceramide.

Ganglioside An acidic glycosphingolipid containing one or more sialic acid groups.

Glycosphingolipid A sphingolipid covalently linked with one or more carbohydrates.

Lysosome An organelle bounded by a single membrane bilayer in the cytoplasm in eukaryotic cells and having an internal pH of 4–5. Lysosomes contain several hydrolytic enzymes and serve as the site for the degradation and recycling of cellular metabolites.

Sphingolipid A lipid with a backbone containing a long-chain sphingoid amine.

Sphingomyelin Catabolism

Sphingomyelinase catalyzes the hydrolysis of sphingomyelin to form phosphorylcholine and ceramide. Ceramide may be further metabolized to form other sphingolipids or may function as a signaling molecule. Sphingomyelinases are categorized into four groups: acid sphingomyelinase (aSMase), secreted sphingomyelinase (sSMase), neutral sphingomyelinase (nSMase), and alkaline sphingomyelinase (bSMase).

aSMase

aSMase is a well-characterized sphingomyelinase with an optimal pH of 5 and localized to lysosomes. The enzyme primarily functions in the degradation of sphingomyelin. In humans, a genetic deficiency of lysosomal aSMase results in Niemann–Pick types A and B, autosomal-recessive lipid storage disorders. The enzyme was purified from urine as a 72-kDa monomeric glycoprotein with a 61-kDa polypeptide core. The human aSMase complementary (cDNA) is encoded by the sphingomyelin phosphodiesterase 1 (*SMPD1*) resulting in a 629-amino-acid polypeptide. The *SMPD1* gene is located on chromosome 11. Metabolic labeling studies in cell-line cells transfected with the human aSMase cDNA reveal that a 75-kDa aSMase precursor is processed by extensive posttranslational modification during sorting to the lysosome.

There is evidence that aSMase plays an important role in ceramide formation after stimulation with tumor necrosis factor (TNF) α , lipopolysaccharide, CD95, or treatment with ultraviolet (UV)-A irradiation. Additional stressors, including ischemia and chemotherapeutic drugs, also activate aSMase and are associated with ceramide-induced cell death. However, the requirement of aSMase in apoptosis and differentiation induced by TNF α and Fas ligand is debated. The involvement of aSMase in ceramide-mediated signal transduction may depend on the cell and tissue type and vary with the stimulus.

sSMase

sSMase is the secretory form of the aSMase gene product and is secreted via a Golgi-apparatus-dependent pathway into the

extracellular space. The enzyme is activated in the presence of physiological concentrations of Zn²⁺ and demonstrates maximum activity under acidic conditions. However, the enzyme is able to hydrolyze sphingomyelin from atherogenic lipoproteins, low-density lipoprotein (LDL) extracted from arteriosclerotic lesions, and oxidized at neutral pH. LDL treated with sSMase forms aggregates that are retained on extracellular matrix and stimulates macrophage foam cell formation. Thus, sSMase may serve a normal physiological function in lipoprotein metabolism and a pathological function in atherogenesis. sSMase activity in plasma is higher in individuals with chronic heart failure and type 2 diabetics compared to healthy individuals. The active circulating form of sSMase may be involved in the formation of atherosclerotic plaques.

nSMase

In mammalian cells, nSMase is a membrane-associated protein with an optimal neutral pH. Although the enzyme is expressed ubiquitously in mammalian tissues, the highest activity is predominantly found in the brain. Mammalian tissues express two isoforms of nSMase. The enzyme activity of the higher molecular weight isoform form is Mg²⁺ dependent but that of the lower-molecular-weight isoform is Mg²⁺ independent. The low-molecular-weight isoforms appear to be degradation products of the high-molecular isoforms. The purified enzyme is activated by phosphatidylserine, Mg²⁺, and Mn²⁺, and inhibited by Cu²⁺, Zn²⁺, Ca²⁺, Cd²⁺, Hg²⁺, glutathione, and asialo-ganglioside, GM3.

Recently, three types of nSMases have been identified in mammalian cells at the gene level. nSMase 1 has a molecular mass of 47.5 kDa and is encoded by the *SMPD2* gene. nSMase 1 was cloned from mouse and human based on multiple sequence alignments of bacterial nSMases. The *SMPD2* gene is located on chromosome 6. The product of the *SMPD2* gene is a membrane-bound Mg²⁺-dependent nSMase, is expressed ubiquitously in mammalian tissues, and localized in endoplasmic reticulum, Golgi and/or the nuclear matrix of cells. The natural substrate of nSMase 1 is still uncertain and the enzyme appears not to be involved in ceramide formation after stimulation by TNF α . Recently, nSMase 1 has been shown to

contribute to the induction of ceramide-mediated proapoptotic signaling under heat stress conditions in zebrafish embryonic cells.

A second nSMase (nSMase 2 encoded by the *SMPD3* gene) with a molecular mass of 71 kDa has been cloned based on phylogenetic analysis. The *SMPD3* gene is located on chromosome 16. nSMase 2 is a brain-specific membrane-bound Mg^{2+} -dependent nSMase with a different domain structure and only marginal sequence similarity to other nSMases. nSMase 2 has the basic properties of rat and bovine brain nSMase and is activated in response to TNF α . nSMase 2 co-localizes with Golgi apparatus markers in a number of cell lines and is activated in response to stress-inducing agents including TNF α , staurosporin, C2-ceramide, and H_2O_2 . However, recent work indicates that nSMase 2 may not be involved in cell apoptosis mediated by TNF α or oxidized LDL.

A third nSMase, nSMase 3, is encoded by the *SMPD4* gene and has a molecular mass of 97 kDa. The *SMPD4* gene is located on chromosome 2. nSMase 3 has only slight homology to nSMase 1 and 2. Similar to nSMase2, nSMase3 is Mg^{2+} dependent, is membrane associated, and has an optimal pH of 7. nSMase3 activity is enhanced in the presence of phosphatidylserine and inhibited by scyphostatin. nSMase3 is ubiquitously expressed and localized to the endoplasmic reticulum as well as Golgi apparatus. In addition, nSMase 3 has been demonstrated to be a TNF-responsive nSMase. An additional nSMase candidate that is encoded by a different gene from nSMase 1, 2, and 3 was expression cloned from human DNA. This nSMase cDNA encodes a 397-amino-acid polypeptide. The enzyme is activated by Mg^{2+} , inhibited by Cu^{2+} and glutathione, and recognizes sphingomyelin as a preferred substrate. The deduced amino acid sequence of the enzyme indicates that the enzyme is a membrane-integrated protein and has a significant homology to the death domain of TNF- α and Fas/AP-1 receptors. The overexpression of this recombinant nSMase in human aortic smooth muscle cells results in apoptosis and augments oxidized LDL-induced apoptosis.

bSMase

The enzyme activity of this SMase was initially found in the small intestine. Recently, bSMase was purified from rat intestine and required bile salt for the enzyme activity. This bSMase with molecular mass of 58 kDa is encoded by the *ENPP7* (ectonucleotide pyrophosphatase/phosphodiesterase family member 7) gene, has an alkaline pH optimal, is Mg^{2+} independent, and is inhibited by orthovanadate, adenosine triphosphate (ATP), imidazole, and Zn^{2+} but not by glutathione. bSMase is a single-pass type 1 membrane protein and has a single anchor domain at C-terminus. The *ENPP7* gene is located on chromosome 17. Expression of this enzyme is specific to the intestinal mucosa. The enzyme is mainly localized to the microvillar membrane in small intestine, in endosome-like structures, and in the Golgi complexes of human enterocytes. In addition, the decrease of the enzyme activity has been shown to be associated with colon cancer. Another type of bSMase with an 85-kDa molecular mass is found in human bile. These enzymes appear to function in the catabolism of dietary sphingomyelin.

Ceramide Catabolism

Ceramidase (CDase) catalyzes the hydrolysis of ceramide to fatty acid and sphingosine. Three types of ceramidase have been described based on their pH optima for activity. These include acid ceramidase, neutral ceramidase, and alkaline ceramidase. Sphingosine and its phosphorylated metabolite, sphingosine-1-phosphate, act as potent inhibitors of protein kinase C and potent effectors of cell proliferation and differentiation. CDase may change the balance of ceramide, sphingosine, and sphingosine-1-phosphate within cells in response to various stimuli. CDase may therefore regulate sphingolipid-mediated signaling events.

Acid Ceramidase

Acid ceramidase (aCDase) can be characterized as an *N*-acylsphingosine deacylase with an acidic pH optimum. The enzyme is localized in lysosomal and endosomal compartments. The enzyme functions primarily in the degradation of ceramide. In humans, a genetic deficiency of lysosomal aCDase results in the lysosomal lipid storage disorder known as 'Farber disease'. The enzyme, purified from human urine, is a 55-kDa heterodimeric glycoprotein consisting of two disulfide-linked polypeptide chains of 13 kDa (α) and 40 kDa (β). The human aCDase cDNA is encoded by the *ASHA1* gene, located on chromosome 8, and predicted to encode a protein consisting of 395 amino acids. The 13-kDa (α) and 40-kDa (β) subunits are derived from a common 55-kDa precursor encoded by the full length of aCDase-cDNA. Only the β -subunit is posttranslationally glycosylated during transport to acidic cellular compartments. aCDase activity is enhanced by an activator protein known as 'saposin D'. aCDase activity increases in response to extracellular stimuli. In rat hepatocytes, aCDase activity is bimodally regulated by interleukin (IL)-1 β and is activated by tyrosine phosphorylation. In renal mesangial cells, aCDase is activated by TNF α but inhibited by nitric oxide. Inhibition of aCDase sustains the accumulation of ceramide induced by TNF α . Overexpression of aCDase in L929 cells suppresses TNF α -induced ceramide formation and cell death.

Neutral Ceramidase

In mammals, neutral ceramidase (nCDase) is present in a variety of tissues and cell types. nCDase activity is mainly found in the membrane fractions. nCDase has been purified from rat brain, where the highest activity is found. nCDase is a 90-kDa membrane-bound, non-lysosomal protein. Similar membrane-bound nCDases, purified from mouse liver and rat kidney, are 94 kDa and 112 kDa monomeric glycoproteins, respectively. The enzyme has a broad pH optimum in the neutral to alkaline range and does not require divalent cations for the activity. The enzyme is stimulated by phosphatidic acid and phosphatidylserine. Partial amino acid sequences of each nCDase were used to clone the genes from mouse, rat, and human. The mouse, rat, and human nCDase cDNAs encode 756, 761, and 782 amino acid polypeptides, respectively.

The human nCDase is encoded by the *ASHA2* gene, which is located on chromosome 10, and ubiquitously expressed. The enzyme is found in the plasma membrane when expressed in HEK293 cells. The mouse nCDase is ubiquitously expressed and at high levels in kidney and liver, and is localized to the plasma membrane. The rat nCDase is expressed in kidney, brain, and heart at high levels. In rat kidney, nCDase is mainly localized at the apical membrane of the proximal tubules, distal tubules, and collecting duct. By contrast, liver nCDase are detected in endosome-like organelles within the hepatocytes. nCDase activity is activated by IL-1 β in rat hepatocytes, resulting in a decrease of ceramide-concomitant with an increase of sphingosine. TNF α stimulates and nitric oxide inhibits nCDase activity in renal mesangial cells.

Alkaline Ceramidase

Alkaline ceramidase activity has been described in human, rat, and mouse tissues. Recently, three alkaline ceramidases have been genetically characterized and show similar protein sequences but have no homology to acid or neutral ceramidases. Alkaline ceramidase 1 (alkaline CDase 1) is encoded by the gene of *ACER1*, consisting of 264 (human) and 287 (mouse) amino acids. Alkaline CDase 1 contains putative transmembrane domains. Alkaline CDase 1 is highly and selectively expressed in skin and localized to the endoplasmic reticulum. Alkaline CDase 1 has pH optimum at 8–8.5 and is activated by Ca²⁺. The enzyme activity is inhibited by Zn²⁺, Cu²⁺, Mn²⁺, and sphingosine. The human *ACER1* gene is located on chromosome 19. Alkaline CDase 1 may regulate the levels of ceramide, sphingosine, and sphingosine-1-phosphate. Recently, alkaline CDase 1 has been shown to mediate growth arrest and differentiation of human keratinocytes through sphingosine-1-phosphate.

Human alkaline ceramidase 2 (alkaline CDase 2) is encoded by the *ACRE2* gene, consists of 275 amino acids, and also contains putative transmembrane domains. Alkaline CDase 2 is ubiquitously expressed at low levels but at higher levels in placenta, and is localized to the Golgi apparatus. The *ACRE2* gene is located on chromosome 9. This enzyme contributes to sphingosine-1-phosphate-mediated cell proliferation and survival through the generation of sphingosine-1-phosphate. In addition, alkaline CDase 2/sphingosine pathway regulates β 1 integrin maturation and cell adhesion. The mouse alkaline ceramidase 2 shows an almost identical protein sequence to the human alkaline CDase 2.

The human alkaline ceramidase 3 (alkaline CDase 3) was originally cloned based on sequence homology to the yeast alkaline ceramidase. The enzyme is encoded by the *ACER3* gene and encodes a protein consisting of 267 amino acids. The enzyme has a pH optimum at 9.5 and is activated by Ca²⁺, but is inhibited by Zn²⁺ and sphingosine. The enzyme hydrolyzes phytoceramide preferentially, is ubiquitously expressed at high levels, and, when overexpressed in COS-1 cells, is localized in both the endoplasmic reticulum and Golgi apparatus. The *ACER3* gene is located on chromosome 11. Alkaline CDase 3 may contribute to the clearance of phytoceramide in mammalian cells but not to the generation of sphingosine from ceramide. The mouse

alkaline ceramidase 3 has an almost identical protein sequence and the same cellular localization as the human alkaline ceramidase 3.

Sphingoid Base Catabolism

At the penultimate step of sphingolipid catabolism, the primary hydroxyl group of the sphingoid base is phosphorylated by sphingosine kinase. The phosphorylated sphingoid base is then cleaved between the vicinal carbons with amino and hydroxyl groups by sphingosine-1-phosphate lyase (SPLase). The predominant sphingoid base in mammalian cells is sphingosine. Sphingosine produced from ceramide by ceramidase is phosphorylated by sphingosine kinase and then degraded to form phosphoethanolamine and hexadecanal by SPLase. The sphingosine-1-phosphate, generated during sphingosine catabolism, is not only a catabolic intermediate but also functions as an extracellular and intracellular messenger. Sphingosine-1-phosphate is mitogenic. The extracellular actions of sphingosine-1-phosphate are mediated through the endothelial differentiation gene (EDG) receptor family of G-protein-coupled receptors, now termed 'sphingosine-1-phosphate receptors'.

Sphingosine-1-Phosphate Lyase

SPLase (SGPL1) is a pyridoxal phosphate-dependent member of a class of enzymes known as 'aldehyde lyases' and cleaves 1-phosphorylated sphingoid bases into aliphatic fatty aldehydes and phosphoethanolamine with a neutral pH optimum. SPLase is a ubiquitous enzyme present in multiple species and mammalian tissues. However, platelets lack SPLase activity, suggesting that platelets may be the primary source of circulating sphingosine-1-phosphate. The enzyme is a membrane-bound protein and in rat liver is localized in the endoplasmic reticulum. The catalytic site and other domains essential for SPLase activity face the cytosol. SPLase cDNAs were cloned from mouse and human based on sequence homology to the *Caenorhabditis elegans* and yeast SPLases. Both cDNAs encode proteins of 568 amino acids. Hydropathy analysis indicates the presence of one transmembrane region near the N-terminus. The human *SGPL1* is located on chromosome 10.

Sphingosine-1-phosphate, a bioactive lipid that is a ligand for a family of G-protein-coupled receptors, regulates a variety of physiological functions. Recent studies have shown that SPLase play a role in cell survival, normal development, stress responses, the maintenance of tissue integrity, and immunity. In addition, SPLase has been demonstrated to function as a tumor suppressor and be involved in lymphocyte trafficking. Unlike mammalian and plant cells, in *Leishmania* patatices, SPLase is responsible for the major route for synthesis of phosphatidylethanolamine, an abundant membrane lipid.

Sphingosine-1-phosphate levels in cells during signaling processes seem to be regulated not only by sphingosine kinase and SPLase but also by a general lipid phosphate phosphohydrolase. In fact, several sphingosine-1-phosphate-specific phosphohydrolases have been identified in yeast and mammalian cells.

Figure 1 Degradation pathways of sphingolipids. The lysosomal diseases caused by genetic defects in a series of lysosomal enzymes and activator proteins for sphingolipid catabolism are indicated in parentheses. NeuAc, *N*-acetylneuramic acid; Cer, ceramide; Glc, glucose; Gal, galactose; GalNAc, *N*-acetylgalactosamine; Gb, globoside; Gb3, globotriaosyl ceramide; SM, sphingomyelin; HO₃SGalCer, sulfatide; Sph, sphingosine; Sph-1-P, sphingosine-1-phosphate; SAP, sphingolipid activator protein.

Glycosphingolipid Catabolism

Glycosphingolipids are components of cellular membranes and are comprised of one or more sugars linked to ceramide. Glycosphingolipids are tissue and cell-type specific. They form patterns that vary with the cell type, stage of growth and

differentiation, viral transformation, and ontogeny. The biosynthesis of glycosphingolipids occurs within the Golgi apparatus where carbohydrates are added by membrane-associated glycosyltransferases. Glycosphingolipids are subsequently transferred to the plasma membrane. At this site they interact with membrane-associated receptors and enzymes as well as

Table 1 Major sphingolipidoses

<i>Disease</i>	<i>Sphingolipid stored</i>	<i>Defective enzyme</i>	<i>Clinical phenotype</i>
Farber	Ceramide	Acid ceramidase	Painful and deformed joints, subcutaneous nodules, hoarseness
Niemann–Pick A and B	Sphingomyelin	Acid sphingomyelinase	Neurodegeneration, hepatosplenomegaly
Metachromatic leukodystrophy	Sulfatide	Arylsulfatase	Blindness, quadraparesis, seizures
Krabbe	Galactosylceramide	Galactocerebrosidase β -galactosidase	Blindness, spastic paraparesis, dementia
Gaucher	Glucosylceramide	β -Glucocerebrosidase	Hepatosplenomegaly, bone infarctions and fractures
Fabry	Globotriaosylceramide	α -Galactosidase A	Parasthesias, renal failure, cerebrovascular disease
Sandhoff	Gangliosides GM2 and GA2, globoside	Hexosaminidase B	Neurodegeneration
Tay–Sachs	Ganglioside GM2	Hexosaminidase A	Neurodegeneration
GM1 gangliosidosis	Ganglioside GM1	GM1 ganglioside β -galactosidase	Neurodegeneration, skeletal dysplasia, hepatosplenomegaly

with bacterial toxins and adhesion molecules and viruses. Following endocytosis, glycosphingolipids are transported to acidic intracellular compartments where they are degraded from the nonreducing ends by a set of lysosomal exoglycosidases that catalyze the stepwise cleavage of their component carbohydrates.

Glycosphingolipid storage disorders are caused by the deficiency of specific glycosidases that are involved in glycosphingolipid degradation (Figure 1). These deficiencies result in the abnormal accumulation of specific glycosphingolipids both in neural and nonneural tissues (Table 1). These disorders vary in terms of their clinical presentations based on the affected organs.

The lysosomal hydrolases that degrade glycosphingolipids of the plasma membrane are water-soluble enzymes. Their activity is dependent on the presence of water-soluble activator proteins termed 'saposins'. The four saposins (A through D) arise from a common precursor protein, prosaposin. Saposin B is an activator for arylsulfatase A, α -galactosidase A, and β -galactosidase. Saposin C is an activator of acid β -glucosidase. Saposin D is an activator of ceramidase. There is no assigned function for saposin A. Glycosphingolipid storage disorders may also arise from inherited deficiencies of the prosaposin as well as from individual saposins.

Arylsulfatase A

Arylsulfatase A catalyzes the desulfation of 3-O-sulfogalactosyl residues in glycosphingolipids. The enzyme activity requires the presence of saposin B as an activator. The ARSA gene maps to chromosome 22 at the end terminus and encodes a 507-amino-acid precursor protein that undergoes posttranslational processing. In addition to N-linked glycosylation required for lysosomal sorting through the mannose-6 phosphate receptor pathway, there is a unique oxidation that occurs for eukaryotic sulfatases. In human arylsulfatase A, a formylglycine residue is found in place of cysteine 69 and is due to the oxidation of a thiol group to an aldehyde. In addition to sulfatide, arylsulfatase A will cleave sulfate groups

from other naturally occurring glycosphingolipids including lactosylceramide-3-sulfate and psychosine sulfate.

β -Galactosidases

β -Galactosidase (GLB1) catalyzes the degradation of galactosylceramide to galactose and ceramide within the lysosome. It also displays activity against galactosylsphingosine and lactosylceramide. The GLB1 gene is localized to chromosome 3p21.33 and encodes a 677-amino-acid protein. The enzyme is more precisely referred to as GM1 ganglioside β -galactosidase and deficiencies are associated with GM1 gangliosidosis. GM1 ganglioside β -galactosidase has an acidic pH optimum. It is activated by chloride ions. The enzyme is isolated as a large-molecular-weight multimer with monomeric units of 65 kDa. This enzyme is also activated in the presence of saposin B. GM1 ganglioside β -galactosidase reportedly catabolizes ganglioside GM1, GA1, lactosylceramide, and keratan sulfate.

Galactocerebrosidase β -galactosidase (GALC) can be isolated as an 80-kDa polypeptide consisting of 50 and 30 kDa subunits. The pH optimum of the enzyme is acidic. The enzyme is active against galactosylceramides that vary in fatty acid chain length and α -hydroxylation. The enzyme is inhibited by sphingosine, ceramide, and galactose. The human gene for GALC maps to chromosome 14q31. Autosomal recessive mutations are associated with Krabbe disease.

β -Glucocerebrosidase

Human acid β -glucocerebrosidase (glucoceramidase) is a homomeric glycoprotein. The GBA gene localizes to chromosome 1q21 and encodes a mature polypeptide that is 497 amino acids in length. Both saposin A and saposin C activate the enzyme *in vitro*. However, only saposin C deficiency is associated with the clinical manifestations of Gaucher disease. Although saposin interacts directly with the enzyme, the association of glycosphingolipids and anionic phospholipids are required for its activity. The pH optimum for the glucocerebrosidase is 5.5. The enzyme is specific for D-glucosyl and not

1-glucosyl forms of glucosylceramide. Activity is reduced by the absence of the C4–C5 *trans* double bond in sphingosine and is minimally affected by the acyl chain length of the ceramide moiety. The disease alleles in Gaucher disease are commonly missense mutations. This results in the synthesis of β -glucosidases with decreased catalytic activity or stability. These typically lead to the type I form of Gaucher disease that lacks central nervous system manifestations. The neuroopathic forms of Gaucher disease (types II and III) are more commonly associated with complete loss of catalytic activity.

α -Galactosidase A

α -Galactosidase A (GLA) catabolizes glycosphingolipids with terminal α -galactosyl groups. These glycosphingolipids primarily include globotriaosylceramide, but are also present in galabiosylceramide and group B blood antigens. Initial studies on the enzyme activity suggested that there were two isozymes termed ' α -galactosidase A and B'. Subsequent work demonstrated that these are two genetically distinct enzymes. α -Galactosidase B is an α -N-acetylgalactosaminidase. Deficiencies in α -galactosidase B are responsible for Schindler disease. Native GLA has a molecular weight of 101 kDa and represents a homodimer with 49 kDa subunits. The enzyme is heavily glycosylated with asparagine-linked high mannose groups. The pH optimum for the glycosidase is acidic. The enzyme is activated in the presence of saposin B. The locus for the human α -galactosidase A gene (GLA) is found at Xq22.

Hexosaminidases A and B

Ganglioside GM2 is degraded in the lysosome by β -hexosaminidase A. This enzyme removes the terminal N-acetylgalactosaminyl residue. The enzyme requires the presence of an additional protein termed 'GM2 activator' encoded

by the GM2A gene. β -Hexosaminidase A is a heterodimer consisting of an α - and β -subunit. The α -subunit is a 55-kDa polypeptide encoded by the HEXA gene found on chromosome 15q23-24. The β -polypeptide varies between 22 and 30 kDa and is encoded by the HEXB gene found on chromosome 5q13. A second enzyme, β -hexosaminidase B, is a homodimer consisting of two β -subunits. Thus, HEXA gene mutations result in loss of β -hexosaminidase A activity, and HEXB gene mutations result in loss of both β -hexosaminidase A and B activities. The β -hexosaminidase A and B enzymes are posttranslationally glycosylated for sorting to the lysosome through the mannose-6-phosphate receptor pathway. They display acidic pH optima as well.

Inherited mutations in HEXA, HEXB, and GM2A all result in the accumulation of ganglioside GM2 and are associated with Tay–Sachs, Sandhoff, and GM2 activator-deficiency diseases, respectively. β -Hexosaminidase B deficiencies are associated with the accumulation of GA2 as well.

Glossary

C-terminal Src kinase (Csk) Kinase that phosphorylates the C-terminal tyrosine residue present on all Src-related kinases, thus inhibiting Src kinase activity.

Protein tyrosine kinase A protein kinase that phosphorylates tyrosine residues in substrates.

SH2 domain A protein module that binds with high affinity to phosphotyrosine residues contained in a defined peptide sequence, with primary specificity usually being conferred to the three residues C-terminal to the phosphotyrosine.

SH3 domain A protein module that binds to sequences that adopt a left-handed type II polyproline helix, typically with a PXXP core.

The Src (sarcoma) family is a group of protein tyrosine kinases closely related to Src. They are nonreceptor kinases, meaning that they lack a transmembrane domain and lie totally within the confines of the cell, although they are associated with cell membranes. Src family kinase activity is regulated by phosphorylation sites within the kinase-domain activation loop and at the carboxy terminus, and by inhibitory interactions between the kinase domain and two other conserved domains, the SH2 and SH3 scaffolding domains. These latter domains can either inhibit the kinase domain or bind other cell proteins, thus helping localize Src to specific subcellular regions and protein complexes while simultaneously regulating Src kinase activity. There are eight Src family members in vertebrates, with different but overlapping expression patterns and, potentially, distinct functions within a given cell. However, there is also extensive genetic redundancy within the family, so inactivating mutations reveal only a subset of the potential cellular and developmental roles of family members. On the other hand, any of a number of different mutations can activate Src kinases, and the resulting deregulated kinase activity has profound effects on cell biology, including malignant transformation of some cell types and increased differentiation of others. At least one Src-like kinase gene is found in every metazoan, including sponges and cnidarians, but is absent, like other tyrosine kinases, from yeasts, protists, plants, and non-eukaryotes. Src kinases are thus one of the ancestral tyrosine kinases and have basic, fundamental roles in cell biology.

History of Src

The history of Src is a story of firsts, and research on Src has spawned wider areas of research. Src was the first protein tyrosine kinase activity to be identified, as a consequence of its role in malignant transformation. In the early twentieth century, P. Rous demonstrated that a chicken sarcoma could be transmitted from bird to bird by a particle smaller than a bacterium, and the field of tumor virus research was born. Rous' virus (RSV) was later shown to contain separable genetic elements for replication and for cell transformation. RSV also was one of the first viruses shown, by D. Baltimore and

H. Temin, to contain RNA-dependent DNA polymerase (reverse transcriptase) activity, consistent with the idea that transformation was caused by a DNA copy of a viral gene for sarcoma (*src*). D. Stehelin, H. Varmus, and J. Bishop, using nucleic acid probes, showed that a gene related to the viral *src* gene was present in uninfected vertebrate cells and was conserved over evolution. This provided evidence for the cellular origin of viral oncogenes. The viral *src* gene is now generally called *v-src*, while the cellular proto-oncogene is called *c-src*, or just *src*. The role of cellular proto-oncogenes in viral and nonviral cancers of animals and humans is now widely accepted.

In 1977, J. Brugge and R. Erikson found that certain antisera from RSV-infected newborn rabbits precipitated a 60 000 Da protein in addition to the virus structural proteins. The gene encoding this protein was shown to be *v-src*, and the protein was named pp60v-*src* or vSrc. It was soon found that this protein contained, or was associated with, a protein kinase activity that would transfer phosphate to antibody molecules or other model substrate proteins. While this kinase was first thought to phosphorylate threonine residues, T. Hunter and B. Sefton soon found that only tyrosine residues were phosphorylated. Indeed, the first tyrosine kinase to be identified was an activity, now known to be due to cellular Src family kinases, associated with the tumor-causing protein (middle T antigen) of polyoma virus (a DNA tumor virus). Both Src and vSrc are tyrosine kinases, but vSrc is 20+-fold more active than Src due to mutations that interfere with the negative autoregulatory interactions that restrain the activity of Src in normal cells. Different strains and derivatives of RSV have vSrc proteins with different numbers of such activating mutations, which have been very informative in understanding how Src is regulated.

The ability of vSrc to cause malignant transformation is thought to be due to unrestricted phosphorylation of substrate proteins that are normally phosphorylated, in a controlled fashion, by Src and other Src family kinases. In addition, the high kinase activity of vSrc may lead to the phosphorylation of other cell proteins that are not normally phosphorylated by Src, but it seems unlikely that these additional substrates are involved in transformation. Similarly, transformation by polyoma virus involves the deregulation of Src, by physical

association between middle T antigen and Src and several other proteins. The consequent unregulated activity of Src is critical for polyoma virus transformation.

While activated vSrc transforms fibroblasts, it causes other effects in other cell types. In some cases, it can induce differentiation and, in others, increase cell migration or morphology changes. These dramatic effects of activated mutant Src or vSrc led to an expectation that endogenous Src would be vital for many fundamental cellular processes.

Functions of Src in Development

The unique functions of Src were revealed when P. Soriano knocked out the mouse *src* gene. Surprisingly, considering the profound effects of activated v-*src* on vertebrate cells, absence of *src* had remarkably mild effects on development *in utero*. However, some defects were detected after birth. Teeth failed to erupt through the gum, and the cranium grew to form a domed shape. Both of these phenotypes are due to increased bone density, attributable to altered osteoclasts, the macrophage-related blood cells that resorb and remodel bone. Detailed studies of *src* mutant osteoclasts indicate that they differentiate normally but have a reduced ability to form specialized adhesion contacts through which they stick to bone and initiate bone resorption. However, blood platelets and neurons, where Src is highly expressed, are not noticeably altered in *src* mutant mice.

Other Vertebrate Src Family Kinases: Redundant and Specific Functions

The mild effects of *src* deletion are partly due to redundancy with other *src* family genes. The *yes* and *fgr* genes were first identified, as with *src*, as oncogenes in various cancer-causing retroviruses. Upon sequencing, they were found to be related to *src*. *lck*, *hck*, *blk*, *lyn*, and *fyn* were cloned by homology. Of the Src family proteins, Src, Fyn, and Yes are widely expressed in many different cell types in the body, whereas Fgr, Lck, Hck, Blk, and Lyn are restricted to, and are more important in, hematopoietic cells. However, alternative splicing and alternative promoter usage (with different coding exons) create additional diversity. For example, one splice form of Fyn is restricted to hematopoietic cells, while another is more ubiquitous. All the Src family proteins contain canonical features of Src that are critical for regulation and localization: the SH3, SH2, and kinase domains, amino-terminal lipid modification sites, and carboxy terminal and activation loop tyrosine phosphorylation sites. Other subfamilies of nonreceptor protein tyrosine kinases include the Csk, Abl, Fes, Tec/Btk, JAK, Syk, and FAK families, which lack one or more features of Src or contain other distinctive domains. The common features of Src family members allow considerable overlap in function, as shown by targeted knockouts and characterization of multiple mutants.

Individual mutation of *fyn* and *yes*, like *src*, causes only mild effects. For example, *fyn* knockouts have several alterations in the brain, including misorientation of pyramidal neurons in cortex and hippocampus and reduced myelination.

In addition, maturation of *fyn* mutant T lymphocytes is impaired. However, more phenotypes are manifested when *src*, *fyn*, and *yes* are mutated in combination. Double mutants have reduced perinatal survival, and triple knockouts survive poorly beyond mid-gestation (embryonic day 9 in the mouse). These triple mutant embryos resemble embryos mutant for the extracellular matrix protein fibronectin or some integrins, suggesting redundant roles for these three Src relatives in adhesive interactions between cells and the extracellular matrix.

The hematopoietic Src family kinases also have redundant and nonredundant functions. Consistent with their restricted expression, none of these kinases is needed for normal development: mice lacking *hck*, *fgr*, and *fyn* are moderately healthy and fertile, as are those lacking *blk*, *fyn*, and *lyn*. However, some hematopoietic defects are detected. Mutation of *lck* alone blocks thymocyte development at a stage prior to a proliferative burst, with a resulting large decrease in T-cell numbers. Macrophages from *hck* mutant mice have impaired phagocytosis. Combined absence of *fyn* and *lyn* leads to autoimmune disease, absence of *blk*, *fyn*, and *lyn* inhibits late-stage B-cell development, and absence of *hck* and *fgr* leads to decreased resistance to bacterial infection. Blood platelets lacking *src*, *hck*, *fgr*, and *lyn* fail to spread on fibrinogen. Thus, important roles for Src kinases in signaling from immunoreceptors and integrins become evident when multiple Src kinases are absent.

The preceding examples indicate that there is considerable redundancy in the Src family (i.e., one kinase can take the place of another if one is missing). However, whether different family members have distinct functions in a given cell remains unknown, because one kinase may normally be dedicated to a specific function but may perform others if another family member is missing.

Cellular Functions of Src Family Kinases: Signaling Adhesion and Immune Responses

The Src family kinases present in hematopoietic cells are activated by a number of stimuli, including integrin ligands, cytokines, and, notably, stimuli that act via immunoreceptors, such as the T-cell antigen receptor on thymocytes and circulating T lymphocytes, B-cell antigen receptor on pre-B cells, and immunoglobulin (Fc) receptors on macrophages. Cell-based assays confirm essential (but redundant) roles for Src kinases in immunoreceptor responses. Current models envisage weak association of Src kinases with the cytoplasmic tails of subunits associated with the immunoreceptors. Clustering of the receptors, possibly associated with altered proximity to protein tyrosine phosphatases (PTPs) and movement into or out of lipid rafts, activates the Src kinase, allowing phosphorylation of tyrosine-containing activation motifs in the immunoreceptors and recruitment of other SH2-domain-containing nonreceptor tyrosine kinases of the Syk and Tec/Btk families. In this situation, the key Src substrate is the immunoreceptor, but Src also contributes to phosphorylation of downstream signaling molecules involved in calcium mobilization and gene expression.

Src, Fyn, and Yes are also activated by adhesive stimuli and by soluble ligands that act via transmembrane receptors of the tyrosine kinase, G-protein-coupled, cytokine, and other

classes. The substrates that are phosphorylated vary according to the type of stimulus and the other proteins recruited by the respective receptor. For example, integrin stimulation causes Src activation and phosphorylation of another tyrosine kinase, FAK. The exact relationship between FAK activation and Src activation is not clear, but probably FAK autophosphorylates and activates Src, which further phosphorylates FAK. Both proteins contribute to phosphorylation of other proteins associated with the integrin. Functionally, absence of Src kinases alters cytoskeletal dynamics, for example, reducing turnover of focal adhesion complexes and slowing cell migration. However, Src activation by integrins also contributes to tyrosine phosphorylation of signaling molecules responsible for stimulating mitogen-activated protein kinase cascades and regulating gene expression. Src kinase activity is also required for cell proliferation induced by soluble growth factors acting via tyrosine kinase receptors. Dissecting the effects of Src activation by the growth factor receptor from the effects of Src activation by integrins is complex, since many cell-cycle events elicited by growth factors depend on cell adhesion via integrins. Src kinase activity can also regulate protein traffic to and from membranes. In relaying such diverse signals, Src family kinases probably have many important substrates, more than one of which may be necessary for an observed biological response. Src kinases thus represent branch points for activation of multiple signaling pathways.

Regulation of Src Kinase Activity

The combined results of mutational and crystallographic analysis have led to a picture of Src as a machine that integrates many different inputs to regulate its conformation and kinase activity (see Figure 1). There are at least two conformational states, simply thought of as on and off. In the off state, the kinase domain is relatively inactive, and the SH2 and SH3 domains are engaged in low-affinity intramolecular interactions. In the on state, the intramolecular interactions are absent, the kinase domain is at least partially active, and the SH2 and SH3 domains are completely accessible for binding other proteins. Thus, in its on state, Src can also potentially act as a scaffold, independent of its kinase activity. For example, Src may bind one protein through its SH3 domain and another through its SH2 domain, bringing the two proteins into a complex that conveys a signal to the cell. However, the extent to which Src kinases have kinase-independent functions *in vivo* when expressed at normal levels is not yet clear.

Src in the on state is only partially active as a kinase, and the kinase domain becomes fully active only when the activation loop is phosphorylated, a reaction that may be intramolecular but that can also be catalyzed by nearby tyrosine kinases, including other Src molecules. Clustering of partially activated molecules may thus increase activation-loop phosphorylation and lead to full activity. Such clustering may be important in regulation of Src family kinases by integrins and immunoreceptors. Conversely, dephosphorylation of the activation loop would reduce Src activity in the cell.

The on and off states are not stable structures, however. Molecular motions at physiological temperature cause these states to be somewhat flexible, allowing the equilibrium to be

disturbed by interactions with ligands for the SH2 and SH3 domains. As the individual intramolecular interactions stabilizing the off state are each rather weak, reduction of any one interaction leads to a concerted transition to the on state. Thus, increasing the local concentration of either an SH2 or an SH3 ligand would be expected to shift the equilibrium toward the on state. This is thought to occur in some situations in which viral proteins (such as polyoma virus middle T antigen and human immunodeficiency virus Nef) are highly expressed. Particularly potent activators would have binding sites for both the SH2 and SH3 domains. As phosphorylation of substrates by the Src kinase can create binding sites for its SH2 domain, Src can be activated by the products of its own kinase activity. Clustering of Src with substrates containing SH3 domain-binding sites may thus activate Src under certain conditions. Removal of such ligands would allow Src to revert to the off state.

In addition to control by clustering and by phosphorylation of the activation loop, another control is provided by phosphorylation of a tyrosine residue in the carboxy terminus of Src. When phosphorylated, this tyrosine serves as a ligand for the Src SH2 domain, stabilizing the off state. Dephosphorylation of this site allows opening of the off-state structure and hence activation. The carboxy-terminal region plays no apparent role when Src is active, and many mutationally activated forms of Src family kinases, found in various oncogenic retroviruses, have deleted or mutated this region. In the cell, a major source of Src regulation is provided by phosphatases that dephosphorylate the carboxy terminus and kinases that rephosphorylate this site. Genetic evidence suggests that the PTP CD45 is key to activating Lck in antigen-stimulated T cells, and that the PTPs RPTP α and Shp2 are involved in regulating Src in fibroblasts. However, to what extent these PTPs are regulated catalytically, and whether they provide a permissive environment in which Src family kinases can be activated by other means, is not clear.

Rephosphorylation of the carboxy terminus is catalyzed by a dedicated protein kinase, Csk, first identified by M. Okada and H. Nakagawa in brain extracts. Csk has few, if any, substrates other than the carboxy termini of Src family kinases. Genetic disruption of *csk* causes hyperactivation of Src family kinases, with consequent developmental abnormalities and death at mid-gestation stage. In *csk* mutant fibroblasts, Src family kinases are activated and the cells are transformed. A close Csk relative, Chk, may also be involved. In *Caenorhabditis elegans* and *Drosophila melanogaster*, Csk relatives can be recognized by sequence, and they are likely to function as Src inhibitors. Csk is structurally similar to Src family kinases but lacks the activation loop and carboxy-terminal tyrosine phosphorylation sites and an amino-terminal lipid modification site. It is thus not regulated like Src family kinases; its location inside cells, however, is regulated. Recent evidence indicates that Csk can bind to, and is activated by, one or more Src substrates (one named Cbp or PAG) that co-localize with activated Src family kinases in membrane subdomains. When these substrate molecules are phosphorylated, Csk is recruited by its SH2 domain, and the Csk is then brought close to the activated Src family kinases. Csk may also be associated, through its SH3 domain, with PTPs that target the activation loop tyrosine of Src. This mechanism would ensure that the Src family kinases

Figure 1 (A) Features of Src family kinases. The N terminus is modified by N-myristoylation and (for most but not all family members) by S-palmitoylation. Conserved structural domains are named SH3, SH2, and kinase (or SH1) domains, proceeding from N terminus to C terminus. In the off-state conformation shown, the SH3 domain is engaged with a linker between the SH2 and kinase domains, and the SH2 domain is engaged with a phosphorylated tyrosine (black circle) near the C terminus. A tyrosine in the activation loop is not phosphorylated (white circle). (B) Different activity states of Src kinases. In both the partially and fully on states, the C-terminal phosphorylation site is dephosphorylated, and the molecule is opened into a flexible conformation with SH3, SH2, and kinase domains available for interactions with other proteins. In the fully on state, the activation-loop phosphorylation site is phosphorylated, the kinase domain undergoes additional conformational changes, and substrates can be phosphorylated with high efficiency. (C) Regulatory interactions of Src kinases with other molecules in the cell. (a) Src can be partially activated by the combined or independent actions of PTPs that dephosphorylate the C-terminal site and protein ligands that can associate with the SH3 and/or SH2 domains. (b) Full activation may occur when partially activated molecules are brought together by clustering of a receptor or by decreased access to a PTP that dephosphorylates the activation loop (not shown). (c) Fully or partially active Src may also act as a scaffold, bringing proteins together but not phosphorylating them. (d) Active Src phosphorylates nearby cell proteins. Partially active Src may also phosphorylate substrates, but less efficiently. Substrates may be associated with the Src SH2 and/or SH3 domains. (e) Src is inactivated by the combined effects of Csk, which phosphorylates the C terminus, PTPs that dephosphorylate the activation loop, and inhibited access to SH2 and SH3 ligands (not shown). Csk may be recruited to Src by interactions with an anchor protein, such as Cbp/PAG. The PTP may also be specifically recruited (not shown). Interactions with regulatory molecules may be affected by movement of Src or the regulatory molecules between different microdomains in the lipid bilayer.

are then turned back off by Csk-catalyzed phosphorylation of their carboxy termini and PTP-catalyzed dephosphorylation of the activation loop.

The activation state of an individual Src kinase molecule in the cell is, thus, the result of a balance between protein–protein interactions and phosphorylation and dephosphorylation of the activation loop and carboxy-terminal tyrosines. However, the activity state (on or off) also affects access by the modifying enzymes. Therefore, there is a complex balance of interactions that allows Src to integrate different inputs. In addition, Src molecules are subject to other posttranslational modifications that regulate activity or localization. In mitosis, Src becomes phosphorylated by Cdk1/Cdc2–cyclin complexes. These serine phosphorylations partially activate Src by reducing the

intramolecular interactions that stabilize the off state. In cells responding to agonists that increase cyclic AMP levels, the cAMP-dependent protein kinase phosphorylates Src and activates it.

Subcellular localization may also be regulated. All Src family kinases are associated with the plasma membrane and intracellular membranes by amino-terminal sequences. The amino-terminal methionine is removed and the next residue (glycine) is subject to N-myristoylation. This modification is cotranslational and not regulated, but the majority of Src family kinases is also subject to reversible, regulated lipid modification by palmitoylation. This modification affects one or more cysteine residues near the amino terminus. Palmitoylation ensures that most Src family kinases (with the exceptions

of Src and Blk) are concentrated in microdomains within the plasma membrane that are enriched in phosphatidylinositol-4,5-bisphosphate, cholesterol, and glycosphingolipids, so-called lipid rafts. These microdomains are also enriched in many signaling molecules, placing the Src kinases close to potentially important substrates and effectors. Cbp/PAG, the aforementioned Csk-recruiting molecule, is also in the lipid rafts. Receptors bearing carboxy-terminal glycosylphosphatidylinositol anchors are localized in the outer leaflet of lipid rafts, and clustering these molecules activates Src family members associated with the inner leaflet. It seems probable that slight changes in protein distribution within lipid rafts will be very important for regulating Src kinase activity and directing phosphorylation activity to the appropriate substrates.

Nonvertebrate Src Kinases and Their Functions

Genetic studies in the fruit fly *D. melanogaster* and nematode *C. elegans*, where there are fewer src genes (two in *D. melanogaster* and one in *C. elegans*), have not revealed distinctive mutant phenotypes. Thus, unlike several other signal transduction pathways, genetic analysis in these organisms has not led the way in understanding how Src is regulated and functions. It is possible that Src proteins in these organisms (as in vertebrates) serve as integrators of many different inputs, and mutations lead to pleiotropic phenotypes. However, one identified function of Src64B in *D. melanogaster* is to regulate cytoskeletal structures in the cells that nurse the developing oocyte, and it does so in concert with a Btk/Tec-related tyrosine kinase. In this regard, it resembles the role of Lck in activating Btk/Tec-related tyrosine kinases in mammalian lymphocytes. Src42A also regulates the actin cytoskeleton in the developing embryo. In *C. elegans*, Src is important in the early embryo for correct cell–cell interactions, which may implicate Src in cytoskeletal organization. Further study in these systems may provide insights into Src regulation and functions in vertebrates.

Summary: Integration of Many Inputs and Regulation of Many Outputs

The many ways to regulate Src family kinases, and the many substrates implicated in different downstream events, position Src family kinases as servants with many masters. In the cell, Src kinases are regulated by the balance of kinases and phosphatases acting at both inhibitory and activating phosphorylation sites, and by proteins that bind to their SH2 and SH3 domains. The proteins that are phosphorylated depend on the subcellular localization and the protein complexes in which the active Src is found, and relay signals to regulate cytoskeletal, membrane, and nuclear events.

Glossary

Fuel homeostasis The steady-state maintenance of fuels.

Gluconeogenesis The synthesis of glucose from nonhexose precursors.

Glycogenolysis The breakdown of glycogen.

Ketogenesis The synthesis of acetoacetate and β -hydroxybutyrate and the generation of acetone.

Starvation The deprivation of any or all of the elements for nutrition.

There is a paradoxical relationship between morbid obesity and starvation because most of the reproducible data regarding fasting metabolism were derived from obese humans undergoing prolonged periods of fasting to reduce their body weight. During starvation, the concentration of blood glucose falls and this decrease is paralleled by changes in the concentration of insulin in the serum. Proteolysis, lipolysis, gluconeogenesis, and ketogenesis ensue. During starvation there develops an orchestrated interplay among the organ systems to produce, select, and conserve fuels needed for body metabolism. Steady-state metabolic processes develop after 18 days of total starvation. Urinary excretion of nitrogen declines to 4–5 g d⁻¹, and ammonium becomes the primary nitrogenous excretory product. Blood substrates and hormones are near constant concentrations, and weight losses and energy requirements are comparable from day to day. Glucose oxidation by the brain is suppressed and the majority of energy is provided by the metabolism of β -hydroxybutyrate and acetoacetate derived from the blood. The liver supplies the large quantity of ketone bodies needed to support the metabolism of the brain, aided in part by a decreased rate of ketone body utilization by skeletal muscle. The kidney also limits the amount of ketone bodies that is excreted in the urine in order to maintain near-electrical neutrality with urinary ammonium. The kidney shares the essential but limited role of gluconeogenesis with the liver. Ketogenesis, gluconeogenesis, ammoniogenesis, ureagenesis, and ketonuria are tightly interrelated during prolonged starvation.

Starvation in humans is the deprivation of any or all of the elements necessary for appropriate nutrition. Several extensive review chapters and books have been written regarding the physiological, biochemical, and psychological observations and measurements made during starvation. However, there is little reliable scientific information relating to weight loss, energy requirements, changes in the concentrations of hormones and substrate in the blood, and to organ metabolism from healthy humans during or after prolonged periods of starvation. Nonetheless, it is possible to draw reasonable conclusions regarding the metabolic effects of starvation in humans.

Food deprivation contrasts with conditions in most industrialized nations today, where obesity is epidemic and threatening the health of an increasing proportion of the population. There is a somewhat paradoxical relationship between starvation and obesity in which overweight people often starve to lose weight.

The cells of the various organ systems require a continuous supply of energy to function. The biochemical mechanisms that maintain the constant availability of fuel to support metabolic functioning are part of a complex system of fuel homeostasis. All mammals store energy when food is available and mobilize the stored fuels during fasting.

This article focuses on the metabolic studies of last century that range from fasting overnight to prolonged starvation. It covers topics such as the loss of weight and energy requirements, the release of stored fuels, the conversion of free fatty acids (FFAs), glycerol, and amino acids into ketone bodies and glucose by the liver, the selective utilization of fuels by the brain and muscle, the conservation of fuels by the kidneys and the promotion of gluconeogenesis, and maintenance of acid–base balance.

Background

The resting metabolic rate (RMR) among humans varies widely. However, general principles of bioenergetics for adult humans, who often have body masses varying over a sixfold range, have been defined. First, the RMR increases as body weight increases; however, the energy requirement per unit weight decreases as body weight increases. Thus, as the weight of a human increases from 40 to 160 kg, the RMR per kilogram body weight decreases from 30 to 15 kcal kg⁻¹ per 24 h. Second, based on total body weight, the RMR of men of a given weight is greater than it is for women. This difference disappears when the RMR is based on fat-free mass (FFM), measured by densitometry. Nonetheless, there is a broad range of energy requirements for people of identical gender and body weight, which is independent of body fat content. It is thus understandable why the quantity and nature of fuels oxidized under near-standard conditions among tens of thousands of human subjects show discrepancies for specific body sizes. However, there is general agreement when the fundamental rules of bioenergetics are applied; this is

[†]Deceased.

Figure 1 The relationship between fat-free mass, determined by hydrodensitometry, and the resting metabolic rate, as determined by indirect calorimetry, in 771 men and women.

illustrated in **Figure 1** which shows the relationship between FFM and RMR in 771 men and women. It should be easier to understand why these data are diverse when the foregoing principles are applied to the analyses of the studies in **Figure 1**. A major advance in our understanding of the mechanisms of survival occurred with the advent of convenient and accurate methods for measuring β -hydroxybutyrate (β -OHB⁻) and acetoacetate (AcAc⁻). These two water-soluble, four-carbon compounds are synthesized from acetyl coenzyme A (CoA) derived from the hepatic oxidation of long-chain fatty acids. Analytical techniques were developed in the laboratories of HA Krebs and co-workers in England. These fuels, along with acetone, are collectively referred to as ketone bodies and are immensely important for sustaining life during starvation.

Detailed clinical studies of the biology of starvation in humans began after 1965 when G.F. Cahill Jr. and colleagues in the United States and elsewhere advanced the concept of fuel homeostasis in humans.

Obesity and Starvation, and Clinical Features of Starvation

It is somewhat paradoxical to note that mechanisms for maintaining the flux of fuels to provide the energy requirements to sustain life during starvation were derived primarily from obese volunteers. These individuals were recruited from the general population or from the hospitalized patients. Most of the volunteers and patients were housed in closely supervised, general clinical research units in hospitals. Those who underwent prolonged periods of starvation received water and, usually, salt tablets and multivitamins. All were studied after an overnight fast or during 3–63 days of total starvation.

A word about the courageous volunteers who made these important studies possible is appropriate. Prolonged starvation of the length mentioned above (up to 63 days) is a difficult physical and emotional experience and the volunteers required an enormous amount of support to complete these studies. Some developed headaches and postural hypotension during the first few days of total food deprivation.

Everyone was preoccupied with hunger as starvation progressed. Understandably, some individuals became cantankerous and withdrew from the studies, and about one-half would manage to rarely sneak bits of food while under close observation, thus spoiling some of the experimental data. Still, most of the volunteers struggled valiantly to comply with the research protocols. These individuals are unsung heroes for their participation in these studies and are owed a great debt of gratitude.

The compensated state of adult obese humans starving for experimental reasons is in sharp contrast to children, adults, and the elderly dying from inanition during famine or confinement in prisons. In the latter individuals, malnutrition is often complicated by other diseases. Understandably, their behavior varies from hostile selfishness to apathy and stupor. Superimposed bacterial, fungal, verminous, helminthic, and protozoal infections, with diarrhea, cough, and protuberant or contracted abdominal walls, modify the clinical characteristics of starving people. The loss of subcutaneous fat and muscle wasting accentuate the size of joints, especially the knees. The calf muscles are among the first to visibly shrink due to limited mobility, and the buttocks show marked atrophy. Hair is broken and brittle and nails split and become pitted and spoon shaped. The skin is pale from anemia, but has regions of pressure hyperpigmentation, fistulae, and decubitus ulcers. Staring, sunken eyes search to identify anything, and the facial musculature is wasted and sometimes taut. Similar features are seen among patients hospitalized with severe malnutrition. Death occurs when about one-third to one-half of the lean body mass is lost in children, or lean and obese adults. In lean individuals, practically all the body fat is mobilized before the irreversible state of malnutrition occurs.

The data from controlled starvation studies may not mimic many of the findings observed in patients from the harsh environments described above. Nonetheless, the data gathered from research centers provide the best-available and reproducible data regarding starvation, metabolism, and fuel homeostasis. These data were collected largely over a period of about four decades. As would be expected, the interpretation of some of the biomedical data changed with the accumulation of more information. An example of this is the changing attitude toward how the kidneys handle ketone bodies. As will be discussed in detail later, ketone bodies have several metabolic roles and are essential for survival during prolonged starvation.

Metabolic Alteration Related to Starvation: Fed to Fasted to Fed

The Fed State

When food is presented to an average hungry human who has undergone a mere 12-h overnight fast, he/she can readily eat at a rate of 150 times the individual's RMR. Only minor perturbations occur in the concentrations of fuels in the blood but the postprandial concentration of insulin, the major anabolic hormone, can increase 50-fold in obese individuals. It may take several hours to digest, absorb, oxidize, and store the excessive caloric content of the food. Some of the nutrients that are consumed in overabundance are transiently stored as glycogen and intracellular amino acids or protein during the early postabsorptive period. However, the dominant

storage form of energy in the body is triglyceride in adipose tissue. A human can consume about as much as 10 000–12 000 kcal d⁻¹ for many days. If this excessive caloric intake continues over a long period of time, the adipose tissue mass can become huge, accounting for as much as 500 000–1 000 000 kcal of energy present as triglycerides. However, the maximum body fat content is usually limited to about one-half of the total body mass. The lean body mass also increases to support the fat mass. Thus, a 150-kg (330 lb) man or woman can have a triglyceride (fat) mass of 75 kg (165 lb). The stored fat, along with some of the body protein and glycogen, is mobilized during semistarvation or total fasting, usually when approximately 20–50 g of carbohydrate and 15–30 g of protein are eaten. However, during total, prolonged starvation among morbidly obese people, when amino acids are continuously mobilized from vital organs (e.g., the heart), death may occur before the entire fat mass of the body is depleted. Thus, grossly obese humans subjected to prolonged starvation can die with body fat remaining.

The Starved State

In going from the fed state to the starved state, the body shifts from storing to mobilizing fuels. The factors that control the production and utilization of specific fuels change rapidly during this transition. In contrast, starving volunteers enter a near steady state of metabolism after 2–3 weeks of starvation, where day-to-day changes are minimal. During starvation, catabolism is tightly regulated and the supply of fuels from various depots adjusts to meet the body's energy requirements. Hepatic glycogen breakdown is brief (only 600 kcal are available as hepatic glycogen in a 70-kg human), while proteolysis is continuous in order to supply amino acids required for gluconeogenesis, for energy, and to maintain acid–base balance. The triglyceride present in adipose tissue is the major and persistent fuel reserve that supports metabolic process during starvation; it can account for as much as 90–93% of the body's energy needs during periods of prolonged starvation.

Refeeding

During the period of semistarvation, a constant awareness of hunger dominates the thought processes of humans. During refeeding after periods of starvation or undernutrition, emaciated people may ingest as much food as possible, sometimes vomiting because of excessive intake. This craving for food persists until weight gain occurs largely from the deposition of fat in white adipose tissue. Eventually, weight gain plateaus and weight loss may occur until the body weight of an individual reaches an equilibrium that is at or near their weight before semistarvation. On the other hand, after total starvation, the obese volunteers who become outpatients experience mild abdominal pain and may pass fecaliths. During the first 2–3 weeks of refeeding, these individuals routinely retain fluid and become edematous and are encouraged to maintain a low caloric intake until diuresis develops. However, the success rate for preventing the reaccumulation of body fat is low. Some clinical investigators hypothesize that the body possesses a set point or has a body fat lipostat. This is questionable because it is just as likely that individuals eat more than they

need to replace body fat, and gain additional weight predominantly as adipose tissue.

Weight Loss, Body Composition, and Energy Requirements

The measurement of body weight is usually obtained accurately and easily. However, edema can complicate the interpretation of this simple measurement. Measuring body composition and energy requirements has several shortcomings. FFM or active tissue (lean body mass) is a conceptualized mass and difficult to measure accurately. This is because there are differences in the loss of mass among different organ systems in both the lean and obese individuals during starvation. The skeletal muscles and subcutaneous fat lose the greatest quantity of weight. Among organs, the liver and spleen lose at least 50% of their usual mass. The gastrointestinal tract becomes atrophic; the diameter of the lumen of the small intestine becomes reduced to 50% of its normal diameter, and the villae become flattened. Gut motility also decreases. The heart decreases in size and the pulse rate and blood pressure decrease. The loss of bone mass is less than the loss of adipose tissue and skeletal muscle during experimental periods of starvation.

The energy needs of the body are determined by the sum of the metabolic requirements of various tissues (brain, liver, muscle, heart, adipose tissue, spleen, leucocytes, etc.) that depend on the mass and activity of individual organs. During the resting state, there is a 50- to 100-fold variation per unit mass for energy requirements among different tissue types (e.g., brain and adipose tissue). The energy requirements of skeletal muscles can change 12-fold in the transition from the resting state to strenuous exercise.

The proposed metabolic efficiency during starvation has long been claimed in lean people, but it has been difficult to demonstrate in starving, obese humans. Studies by Owen and colleagues differ from those of Leibel and associates in this regard. There is no question that as body size decreases in lean and obese humans, their metabolic requirements also decrease. Nonetheless, metabolic adaptation to starvation, where the energy requirements per unit of measurement decrease out of proportion to changes in unit of measurement, remains a perplexing issue. This is partly due to the method by which the data are calculated or expressed. The non-RMR is more difficult to measure and is more inaccurate than estimates of the resting energy expenditure. Therefore, if there is an adaptive metabolic efficiency induced by food deprivation, it should be demonstrable by the (more) standardized RMR measurement. However, this has not been consistently demonstrated in all studies. Therefore, the increase in efficiency may be more apparent than real.

Thus, there remains an inadequately defined relationship between weight loss and metabolic rate. There are contradictory data as to whether there is a decreased RMR per unit mass in adult men produced by prolonged semistarvation. However, the normal RMR varies widely from low, normal, or high values for humans of identical weight, gender, and age. Therefore, it is not surprising that the literature on RMR for humans, based on the standard of measurement, is inconsistent. For example, differences among the various thyroid hormones,

T_4 , T_3 , and rT_3 , in lean and obese people subjected to protracted food deprivation may influence the RMR. It is well known that after about a week of total starvation, when the diuretic phase of starvation is completed, body weight loss was only 0.32% per day. Later in starvation the RMR of obese, starving volunteers, based on oxygen consumption per kilogram FFM per day, and corrected for urinary nitrogen loss during starvation, is constant. This was truly disheartening for obese people who desperately wanted to lose body fat. It also clearly demonstrates how limited total starvation is as a method for weight reduction for morbidly obese patients. Nonetheless, critical knowledge regarding the metabolic effects of starvation has been obtained from these noble volunteers.

The Nature and Quantity of Fuels Oxidized during Starvation

Indirect calorimetry closely reflects the nature and quantity of the fuels oxidized. The results obtained using this method are influenced by dietary intake, total metabolic requirements, and state of physical activity. When lean individuals fast overnight, their nonprotein respiratory quotient (npRQ) is 0.84. This matches the previous day's intake of 12–20% protein, 40–45% fat, and 40–45% carbohydrate. When obese people eat the same balanced diet, but with a greater caloric intake to match their greater metabolic needs, the npRQ is significantly lower and decreases as body weight increases. Figure 2 shows the trend in the nature and quantity of fuels oxidized after an overnight fast in lean and obese humans. The data show that as weight and body fat increase, the npRQ falls. The greater the RMR, the greater the quantity of fat that is mobilized to meet the energy requirements of fasting humans. Due to body energy demands, obese humans shift into an accelerated rate of fat mobilization. However, this tendency to mobilize and oxidize stored fat becomes more obvious in both lean and obese people as fasting is prolonged. As starvation is extended to 2–3

days and beyond, lipids furnish 90–93% of the resting energy requirements in both lean and obese humans. These changes in the nature and quantities of fuels oxidized by tissues, such as liver, muscle, and brain, act to spare glucose from oxidation; this provides the physiologic basis for insulin resistance when carbohydrate oxidation must be curtailed for survival during food deprivation.

The absolute minimal rates for the major fuel utilization before death occurs have not been defined. The minimum requirement for fat and protein oxidation in $\text{g d}^{-1} \text{kg}^{-1}$ FFM has been approximated as follows: $2.98 \pm 0.21 \text{ g kg}^{-1} \text{ d}^{-1}$ FFM for fat; $0.52 \pm 0.10 \text{ g kg}^{-1} \text{ d}^{-1}$ FFM for protein. Glucose is derived from glyceride-glycerol, amino acids, propionate, and recycled lactate and pyruvate. About $1.91 \pm 1.04 \text{ g kg}^{-1} \text{ d}^{-1}$ FFM are synthesized. However, most of the glucose that is synthesized during starvation is recycled from lactate and pyruvate (the Cori cycle) or made from glycerol, alanine, and glutamine. The quantity of glucose that undergoes oxidation to CO_2 and H_2O is primarily determined by the catabolism of glucose in the central nervous system (CNS) and to a lesser extent by the red blood cells. This quantity is not closely related to the FFM because the size of the brain is unrelated to the FFM. The terminal oxidation of glucose is $40\text{--}45 \text{ g d}^{-1}$, which is derived primarily from gluconeogenesis from amino acids (alanine and glutamine) and glycerol.

In obese humans, during starvation there is no decrease in the metabolic requirement per unit mass, based on measurements of oxygen consumption. However, when the npRQ decreases below 0.7, the theoretical minimum for fat oxidation, there is a difficulty in extrapolating the respiratory exchange rates of O_2 and CO_2 and urinary nitrogen excretion into energy expenditure. The production of CO_2 falls disproportionately to O_2 consumption, creating a mysterious situation characterized by a calculated npRQ of 0.62–0.65. This unusual finding cannot be eliminated by correcting for ketonuria. However, it has been postulated that some of the fatty acids released from triglyceride stores may undergo desaturation before being recycled to storage depots. The process of desaturation consumes oxygen and produces heat, but releases no carbon dioxide. Desaturated FFAs in the blood have been identified in starving animals. If this process occurs in humans, the respiratory quotient (RQ) should rise before death, when unsaturated fatty acids are released and oxidized for energy. The RQ does rise in animals and humans during the premortal period of starvation. This phenomenon has not been fully explained but is usually attributed to the mobilization and oxidation of amino acids. It is just as likely that it is due to oxidation of desaturated fatty acids.

Figure 2 The nature and quantity of fuels oxidized by humans after a 12–14-h fast. Fat oxidation increases as body size increases.

Changes in the Concentration of Substrates and Hormones in the Blood

The concentration of glucose in the blood after an overnight fast is 4.5 mM; this value falls to 3.6 mM after 3 days of starvation. Thereafter, the concentration of glucose in the blood reaches a plateau. Anaerobic glycolysis in tissues such as muscle, brain, red blood cells, and kidney medulla converts glucose into lactate and pyruvate, and the liver extracts these compounds to produce glucose. The concentration of lactate in

the venous blood is less than 1.0 mM, while the concentration of pyruvate is less than 0.1 mM and is constant in the resting state. The concentration of FFA in the plasma rises from 0.6 to 1.4 mM during the first few days of starvation. Thereafter, the concentrations of these fuels remain elevated and relatively constant. The rate of uptake and disposal of FFA is largely determined by its concentration in the blood. Insulin regulates the release of FFA from adipose tissue, primarily by influencing lipolysis, and thus the availability of FFA. The concentration of glycerol in the blood derived from lipolysis is less than 0.1 mM after an overnight fast and rises to 0.15 mM on the third day of starvation. Thereafter, glycerol remains constant because uptake, primarily by the liver, to synthesize glucose matches its release by adipose tissue. The concentration of triglycerides in the blood is less than 1.0 mM and remains constant during fasting.

A characteristic of fasting in humans is the presence of increased concentrations of ketone bodies in the blood (Figure 3) and urine. These water-soluble, short-chained organic acids are synthesized primarily in the liver from the acetyl CoA derived from fatty acid oxidation and serve as alternate fuels for tissues such as the brain. Ketone bodies replace glucose as the dominant energy source for the brain as starvation progresses. Physical activity augments catabolism during starvation and promotes hyperketonemia. No other fuel in the blood changes as markedly as the concentration of ketone bodies during starvation. This is partly due to the low concentration of ketone bodies in the blood during the

postprandial period, after a mixed meal containing adequate carbohydrate. After an overnight fast, lean people have blood AcAc^- and $\beta\text{-OHB}^-$ concentrations of 0.05 mM, while this value is slightly higher in obese individuals. Acetone is virtually absent after an overnight fast, unless the individual is regularly consuming a high-fat diet. There is an exponential rise in the concentration of AcAc^- and $\beta\text{-OHB}^-$ in the blood during starvation, until a new steady level develops. During the first 3 days of fasting, the AcAc^- concentration in the blood increases to 1.5 mM, while $\beta\text{-OHB}^-$ continues to rise to 4.5 mM after day 10 of starvation. AcAc^- plus $\beta\text{-OHB}^-$ reaches a plateau at 6–8 mM after 18 days of total starvation (water, salt, and vitamins were provided). The smell of acetone halitosis becomes evident after 2–3 days of starvation when the blood concentration is 0.25 mM. Acetone slowly increases to 0.35 mM after 21 days of starvation. A minimum estimate of the change in the concentration of ketone bodies in the blood from an overnight fast to 18 or more days of total starvation can be as great as 60-fold. Blood AcAc^- and $\beta\text{-OHB}^-$ are anions and the hydrogen produced during ketogenesis combines with bicarbonate to form CO_2 and water. CO_2 is exhaled, thus decreasing the concentration of bicarbonate in the blood; this creates the typical anion gap of ketonemia. Blood pH also falls appropriately (7.4–7.3), and a mild metabolic acidosis of starvation becomes evident.

The concentration of total amino acids in the plasma declines slowly from an overnight fasting value of 4.6 to 3.7 mM after 40 days of starvation. However, there are four basic patterns of change among the amino acids during total starvation, represented by alanine, glycine, valine, and glutamine. Alanine rapidly decreases to 30% of its overnight concentration. Glycine does the opposite; it rises nearly threefold, before reaching a plateau. The concentration of valine doubles in the plasma during the first 7–10 days of starvation, and then slowly and progressively falls to a value below its overnight fasting value. Venous glutamine, the predominant plasma amino acid, remains relatively stable during 5–6 weeks of fasting. Blood urea nitrogen mimics the concentration of alanine in the blood. The concentration of creatinine in the blood slowly drifts downward, reflecting the decrease in muscle mass.

Figure 3 Changes in the concentration of ketone bodies and free fatty acids (FFAs) during starvation.

Hormonal Changes

Insulin is the main hormone that controls the anabolic processes that maintain fuel homeostasis in humans. Its secretion is primarily regulated by the blood glucose concentration, but the levels of amino acid, FFA, and ketone bodies also modulate insulin release by the β -cells of the pancreas. The influence of insulin on the metabolism of the major organs is readily demonstrated in adipose tissue, skeletal muscle, liver, white blood cells, and other tissues. Insulin also inhibits the secretion of glucagon, a significant counterbalance catabolic hormone.

The concentration of insulin in the blood parallels the changes in the levels of glucose. The fall in the concentration of insulin diminishes some of its inhibitory effects on peripheral proteolysis and lipolysis. In the starved state, the concentration of insulin falls, resulting in a decrease in the rate of uptake of glucose, amino acids, and fatty acids in peripheral

tissues, and a subsequent increase in the rates of gluconeogenesis, lipolysis, and proteolysis. After an overnight fast, the concentration of insulin in the portal blood is 2–3 times greater than the peripheral venous concentration. After 2–3 days of starvation, the portal–peripheral insulin concentration gradient is small; however, there is still a high-enough concentration of insulin in the blood to limit the maximal rates of glycogenolysis, gluconeogenesis, and ketogenesis. In addition, insulin has at least two indirect effects on hepatic glucose and ketone body production. Insulin decreases the delivery of gluconeogenic precursors and FFA from the extrahepatic tissue stores to the liver. As the concentration of insulin in the mesenteric blood decreases, the inhibitory effect of insulin on the β -cells of the pancreas curtails the secretion of glucagon. Thus, the low concentration of insulin in the blood promotes glucagon secretion.

Insulin has dual roles in controlling the release of glucose and ketone bodies from the liver (and kidney cortex), amino acid from muscle, and FFA from adipose tissue. Glucagon has the opposite effect. It augments hepatic (and renal) gluconeogenesis and ketogenesis, and promotes peripheral lipolysis and proteolysis. A relatively low blood insulin concentration and relatively high glucagon concentration creates a blood insulin/glucagon ratio that promotes fuel availability. These pancreatic hormones serve collectively to finely balance the fuel needs of various tissues. The catabolic role of glucagon is augmented by catecholamines, glucocorticoids, and growth hormones. As fuel homeostasis is critical for survival, there are multiple levels of hormonal control of this process.

Appetite Regulation

During starvation, there are a number of factors that regulate the control of appetite. Ghrelin, an orexigenic hormone, primarily secreted by the stomach and duodenum, normally increases in the blood before meals and falls after meals. Ghrelin is thought to stimulate hunger, increase body weight, and decrease metabolic rate. It rises with semistarvation but its physiologic roles regarding hunger need further elucidation. Adipose tissue produces a satiety hormone, leptin, which suppresses appetite. The leptin concentration in the blood falls in parallel with insulin during the first 3 days of starvation. As body fat decreases during starvation, the blood leptin concentration decreases. A fall in the levels of leptin in the blood increases the hypothalamic concentration of neuropeptide Y, greatly stimulating appetite. However, the control of appetite is not a simple process, but rather involves the interaction of a number of neuroendocrine systems. There is no single hormonal neuropeptide that controls hunger in a starving human. Prolonged starvation causes exaggerated hunger, a psychosomatic state that dominates the conscious mind.

Insulin plays an important role in the regulation of appetite. Acting together with leptin, insulin circulates at concentrations proportional to the body fat content. Both hormones enter the CNS and bind to specific receptors in neurons involved in controlling food intake. The administration of leptin and insulin directly to the hypothalamus decreases appetite and suppresses food intake. It is probable that leptin is the more important of the two hormones since leptin deficiency, not a lack of insulin, results in obesity. The mechanism

by which these hormones influence the CNS is the subject of intensive study. A detailed discussion of this area is beyond the scope of this article. However, it should be clear that during starvation, as the mass of adipose tissue decreases and the secretion of insulin by the pancreas is depressed due to a lack of food intake, the appetite centers of the brain would be stimulated by the lack of satiety signals such as leptin, insulin, and ghrelin.

Adipose tissue secretes a number of other regulatory peptides, besides leptin, that control fuel deposition. These include adiponectin, resistin, adipisin, acetylation-stimulating protein, angiotensinogen, and cytokines. The most abundant adipose-specific hormone is adiponectin. The concentration of adiponectin in the blood is positively correlated with insulin sensitivity. Adiponectin promotes glucose uptake in muscle and fatty tissue. Its concentration in plasma is inversely related to adipose tissue mass, especially abdominal fat mass. The levels of adiponectin in the blood fall during semi-starvation and total starvation, when glucose intolerance has been documented. Overexpression of the gene for adiponectin in the mouse results in profound obesity in the animal, underlining the importance of this hormone in the control of lipid deposition. Resistin is another protein secreted into the blood by adipose tissue, but it has an effect that is opposite to that of insulin. Its concentration in the blood of humans after prolonged starvation has not been defined. The behavior of adipose tissue cytokines in humans during weight reduction caused by semistarvation is under investigation.

Biochemical Changes during Starvation

Starvation induces a number of specific biochemical changes that permit an individual to survive in the absence of food for a prolonged period of time. These include alterations in glucose synthesis, fatty acid utilization by specific tissues, and the preservation of nitrogen to insure the maintenance of lean body mass. Starvation is a catabolic state in which fuel reserves are mobilized to support metabolic needs. To understand the metabolic adaptations to starvation, it is first necessary to describe the available energy reserves of a human as starvation begins. It has been estimated that a 70-kg human contains 144 000 kcal as fat (largely as triglyceride), 24 000 kcal as protein (lean body mass), and only 900 kcal as carbohydrate (liver and muscle glycogen). The relatively low level of carbohydrate reserve in humans necessitates a number of biochemical adaptations to insure the appropriate energy supply to specific tissues. For example, the brain uses 600 kcal of glucose each day; this means that the total carbohydrate reserve is depleted in about 1 day of starvation! It is clear that mechanisms must exist for the use of fuels other than glucose (fatty acids and ketone bodies) by tissues such as the muscle and the brain, to insure survival during starvation. This process is called fuel sparing.

Control of Fatty Acid Release during Starvation

Since fat is the major caloric reserve in humans, the regulation of FFA mobilization from adipose tissue during starvation is a critical factor for survival. The breakdown of triglyceride via lipolysis is under the control of a number of hormones,

including epinephrine, glucagon, glucocorticoids, and insulin. The concentration of insulin in the blood falls by 50% after 3 days of starvation. At the same time, there is an increase in the concentration of glucagon. This change in the insulin-to-glucagon ratio is a critical factor in the increase in lipolysis and the enhanced rate of hepatic and renal gluconeogenesis that occurs during starvation. Insulin is the major antilipolytic hormone and its decrease is the major factor in insuring the increased availability of the fatty acids needed for energy metabolism during starvation.

Adipose tissue contains a hormone-sensitive lipase that is sensitive to the state of its phosphorylation. An increase in the concentration of cyclic adenosine monophosphate (cAMP) in the tissue (caused by a rise in epinephrine, norepinephrine, and growth hormone, and a drop in the level of insulin) activates protein kinase A (PKA) that in turn phosphorylates, and thus activates the hormone-sensitive lipase; this results in the breakdown of triglyceride and generation of FFA. Insulin counters this process, partly by decreasing the levels of cAMP in the adipose tissue, and by increasing the activity of a phosphoprotein phosphatase that dephosphorylates the hormone-sensitive lipase, thereby inactivating it. There is also evidence that insulin increases the activity of a phosphodiesterase in the adipocyte, causing a fall in the concentration of cAMP in the tissue. The net result of prolonged starvation is an enhanced rate of FFA release from adipose tissue that is used as a fuel by a number of tissues.

About 50% of the plasma FFA mobilized to the liver during starvation is extracted and 50–80% of the extracted fatty acids undergo partial oxidation to synthesize equal quantities of AcAc^- and $\beta\text{-OHB}^-$; most of the remaining quantity of FFA is converted to triglycerides and recycled to adipose tissue as very low density lipoprotein (VLDL). It is interesting that such a large fraction of the FFA released by lipolysis is re-esterified back to triglyceride in adipose tissue or in the liver and other tissues, and returned to the adipose tissue for the resynthesis of triglyceride. Fatty acid recycling via this so-called triglyceride–fatty acid cycle can account for as much as 60% of the fatty acid released after 3–4 days of starvation in humans. The synthesis of triglyceride requires the generation of 3-phosphoglycerol, usually from glucose. During starvation, when glucose is at a premium, the 3-phosphoglycerol is generated from pyruvate, lactate, and amino acids via an abbreviated version of gluconeogenesis termed ‘glyceroneogenesis’. The triglyceride/fatty acid cycle is a futile cycle that uses energy for the synthesis of triglyceride (six molecules of adenosine triphosphate (ATP) per molecule of triglyceride synthesized), so it must have a role in preserving the FFA that was released by adipose tissue to be used later as a fuel by peripheral tissues.

Proteolysis and Amino Acid Metabolism

After a meal containing proteins, amino acids largely escape hepatic extraction and are carried by the blood to extra-hepatic tissues. Insulin promotes the active transport of amino acids into cells, primarily skeletal muscle. Normally, amino acids are in a state of flux; they are precursors for protein synthesis and then appear as free amino acids after protein breakdown. Within the first day of starvation, however, protein catabolism dominates

the metabolic flux. As starvation progresses, relatively more proteolysis occurs and amino acids are mobilized from protein depots. The dominant fate of the carbon skeletons and the amino and amide groups, derived from the breakdown of amino acids in muscle, is conversion to alanine and glutamine that is mobilized from muscle and other depots and transported to liver and kidney to be utilized to synthesize glucose, urea, and ammonia.

Protein catabolism in the splanchnic tissues is somewhat less responsive to insulin than it is in skeletal muscles. In the periphery, the basal concentration of insulin that is present during starvation limits proteolysis. Nonetheless, glucose must be continually synthesized from amino acids by the liver and kidney cortex during starvation; amino acids from muscle protein are a major source of carbon for gluconeogenesis. The first proteins degraded during starvation are the digestive enzymes secreted from the stomach, pancreas, and small intestine. The liver also loses various enzymes needed to process incoming nutrients into plasma protein (e.g., albumin). Thereafter, the largest protein mass of the body, striated muscle, begins to be drained, not only of intracellular proteins, such as enzymes, but also of contractile elements. The disintegrating muscles can easily be seen as skeletal muscle atrophy during prolonged starvation in humans.

The control of proteolysis in muscle is a complex process. Insulin retards proteolysis and enhances protein synthesis. In addition, metabolic acidosis promotes protein breakdown to insure the generation of ammonia to titrate the acidity of the tubular urine. The low plasma insulin concentration and mild metabolic acidosis of starvation are conducive to proteolysis. The best-characterized pathway for protein catabolism is an ATP-independent system of acid proteases (cathepsin) and hydrolases contained in cellular lysosomes. In addition, there are calcium-dependent proteases, as well as cytosolic ATP-dependent and -independent pathways. The most important muscle proteolytic system employs the ubiquitin proteasome pathways.

Amino acids generated from proteolysis undergo deamination and/or deamidation before being further transformed to alanine or glutamine, which efflux from skeletal muscle. Alanine plus glutamine account for 80% of the amino acids released from muscle after prolonged starvation, and are the principal vehicles for transporting nitrogen from peripheral tissues to liver and kidney. These two amino acids together account for only 10% of the composition of skeletal muscle protein, but they provide the majority of the carbon for the synthesis of glucose by the liver and kidney during starvation. Thus, there is a net conversion of other amino acids into alanine and glutamine in the muscle. Alanine is the major nitrogenous compound released from muscle and extracted by the liver for gluconeogenesis and ureagenesis. There is a glucose–alanine cycle between muscle and liver. Glutamine is the other amino acid released in high levels by muscle, but it is extracted from the blood by the small intestine, where it is converted to alanine for subsequent use by the liver, or by the kidney cortex, producing glucose and ammonia. During the catabolism of muscle protein, branched-chain amino acids provide the amino groups to α -ketoglutarate to form glutamate via the enzyme branched-chain aminotransferase; glutamine is derived from glutamate and ammonia by the action of glutamine synthase.

The tricarboxylic acid (TCA) cycle is the key metabolic pathway for energy production: acetyl CoA is oxidized to carbon dioxide in the cycle. During starvation, the TCA cycle has another fundamental role in metabolism. Amino acids are catabolized to 4- (aspartate, asparagine, phenylalanine, tyrosine, methionine, isoleucine, and valine) and 5- (glutamine, glutamate, histidine, proline, and arginine) carbon intermediates that enter the TCA cycle by a process termed anaplerosis. The TCA cycle cannot serve as a carbon sink; therefore, the carbon skeletons that enter the cycle must leave by a process called cataplerosis. Anaplerosis and cataplerosis are reciprocal reaction pathways that must be in balance. These reactions have been reviewed in detail elsewhere in this volume. It is important to note that during starvation more fuels are released from storage depots or synthesized in the liver and kidney than are oxidized to generate energy. About 60% of the fuels that enter the bloodstream are recycled, for example, FFA, glucose, and amino acids, especially alanine and glutamine.

Ketogenesis

The liver not only stores glucose as glycogen, but also converts fuels such as FFA, amino acids, lactate, pyruvate, and glycerol to glucose and ketone bodies and detoxifies the ammonia, which is produced from the deamination of amino acids, by converting it to urea. After an overnight fast, hepatic glycogenolysis, gluconeogenesis, and ketogenesis provide 50% of the total energy-yielding fuels for the body in the resting state. Lipolysis of triglyceride in adipose tissue supplies FFA and glycerol; these substrates become precursors for ketone body (fatty acids) and glucose (glycerol) syntheses. Amino acids released primarily by skeletal muscles complement glycerol as gluconeogenic precursors. As fasting is prolonged, the kidney cortex also contributes to fuel homeostasis by conserving substrates and sharing the gluconeogenic role with the liver.

Ketone bodies are the only fuels synthesized in the body that do not recycle. Unlike FFA, amino acids, and glucose, ketone bodies are either oxidized or excreted in the urine and/or the breath (acetone); only a negligible small amount of acetone can be converted to glucose. β -OHB⁻ and AcAc⁻ are synthesized in liver (and kidney) mitochondria by the following reactions. Two molecules of acetyl CoA condense head to tail to form acetoacetyl CoA; this reaction is catalyzed by acetoacetyl CoA thiolase. Another molecule of acetyl CoA is joined by β -hydroxy- β -methylglutaryl CoA (HMG CoA) synthase to form HMG CoA, also generating a hydronium ion (H⁺). HMG CoA lyase cleaves HMG CoA into AcAc⁻ and acetyl CoA. AcAc⁻ is then reduced to β -OHB⁻ by β -hydroxybutyrate dehydrogenase. Acetone and CO₂ are formed from the nonenzymatic degeneration of AcAc⁻. While the great majority of ketone bodies are synthesized from the acetyl CoA that is derived from the β -oxidation of fatty acids in the mitochondria, a small quantity can be synthesized from ketogenic amino acids during starvation. In addition, acetoacetyl CoA can be formed from FFA and cleaved to AcAc⁻ in the kidneys. The hepatic production of β -OHB⁻ and AcAc⁻ is about equal; however, during hyperketonemia, the concentration of β -OHB⁻ in the blood is 3 times greater than AcAc⁻. This is due to the decreased nicotinamide adenine diphosphate

(NAD)/NADH ratio in the hepatic mitochondria, which favors the reduction of AcAc to β -OHB⁻ and the preferential removal of AcAc⁻ or conversion of AcAc⁻ to β -OHB⁻ by skeletal muscle. The brain removes β -OHB⁻ and AcAc⁻ in a concentration-dependent manner.

The metabolism of ketone bodies during starvation is a critical element in the control of fuel homeostasis in humans. The demonstration that β -OHB⁻ and AcAc⁻ could serve as major fuels for the metabolism of the brain during starvation was a critical factor in evaluating the roles of fatty acid oxidation, amino acid mobilization, glucose conservation, and urinary nitrogen excretion during prolonged starvation. From this research it became clear that the abundance of FFA stored in human tissues provides a substantial reserve for the synthesis of ketone bodies. The metabolism of ketones by the brain during starvation greatly limits the need to use amino acids to make glucose to support the metabolism of this tissue. This is an important example of fuel sparing.

There are few synthetic processes that are quantitatively as large as the daily rate of ketogenesis during starvation. After an overnight fast, hepatic ketogenesis amounts to 10 g d⁻¹. After 2–3 days of starvation, the liver synthesizes over 100–150 g d⁻¹ of ketone bodies. Over this period, the average resting human oxidizes a minimum of 3 g of fat per kg FFM per day. Thus, a large, but not obese adult man, weighing 80 kg, with a body composition of 80% FFM (64 kg) and 20% fat mass (16 kg) oxidizes a minimum of 192 g of fat per day. About 60 g of the FFA derived from the lipid stores undergo β -oxidation in the liver to yield an estimated 113 g d⁻¹ of ketone bodies. The 90% of these water-soluble fuels undergo terminal oxidation, primarily by the brain and muscle. Most of the remainder is excreted in the urine. It is interesting to note that about half of the molecular weight of AcAc⁻ and β -OHB⁻ is oxygen. Thus, if 10–12 g of ketone bodies were excreted in the urine, only 5–6 g of the carbon skeleton would be derived from stored triglycerides. Since β -OHB⁻ and AcAc⁻ are excreted with near equimolar quantities of NH₄⁺, ketosis is an energetically cheap way to excrete nitrogen (the synthesis of urea requires four molecules of ATP per molecule of urea). Finally, for each gram of nitrogen lost in the urine 3.57 g of glucose is synthesized.

Gluconeogenesis

The *de novo* synthesis of glucose from nonhexose precursors (gluconeogenesis) occurs in the liver, kidney cortex, and, perhaps to a minor extent, in the small intestine. The precursor molecules for gluconeogenesis, and the organs involved in this process, change as starvation progresses. After an overnight fast, the liver is the primary, if not the sole, organ that makes a net contribution to glucose in the blood. The kidney extracts and releases glucose after an overnight fast, but its overall contribution is minimal. After 3 days of starvation, renal gluconeogenesis increases and by 10–18 days of total starvation the kidney contributes 50% of the glucose added to the blood. However, during prolonged starvation, total glucose added to the blood from gluconeogenesis is only 50% of what it was after an overnight fast when gluconeogenesis is greatly complemented by hepatic glycogenolysis. In addition, during prolonged starvation, only half of this glucose contributed to the

Figure 4 Schematic representation of fuel delivery by the liver and kidney during starvation. Hepatic gluconeogenesis, glycogenolysis and ketogenesis, and renal gluconeogenesis are expressed as $\text{mmol min}^{-1} 1.73 \text{ m}^{-2}$ and converted to calories per 1.73 m^2 body surface area. Hepatic glycogenolysis is rapidly dissipated during the first 1–3 days of fasting. The liver and kidney share the role of gluconeogenesis as starvation progresses. Hepatic ketogenesis becomes a dominant mechanism for supplying fuels to the blood after liver glycogenolysis is curtailed. Renal ketogenesis may contribute to ketonuria, but not to ketonemia.

blood is oxidized to CO_2 and H_2O . This is the result of the sparing of glucose by tissues that use more abundant fuels such as ketone bodies.

A schematic representation of the quantities of ketone bodies and glucose contributed to the blood by the liver and kidneys is shown in **Figure 4**. In general, glycogenolysis decreases as gluconeogenesis increases, and glucose production decreases as ketogenesis increases. An interesting aspect of gluconeogenesis during starvation is the relationship between renal gluconeogenesis and ammoniogenesis. Glutamine produced by the muscle is used by the kidney cortex as the major source of carbon for gluconeogenesis. The amino and amide groups are removed from glutamine to form α -ketoglutarate, which then enters the TCA cycle and is converted to glucose via renal gluconeogenesis. The kidney also has the ability to synthesize glucose from lactate, pyruvate, glycerol, amino acids, and other precursors, but only glutamine has been closely associated with net renal gluconeogenesis.

The decreased rate of glucose production during starvation is linked to the increased ketone body production. Hyperketonemia is accompanied by ketonuria and ammoniogenesis. Renal NH_4 production is coupled to renal gluconeogenesis, while the release of NH_3 by the kidney is linked to hepatic urea production. In summary, gluconeogenesis, ketogenesis, ammoniogenesis, acid–base balance, and ureagenesis are all tightly interdependent during starvation.

Urinary Nitrogen Excretion

Total, daily urinary excretion undergoes an asymptotic, progressive decrease during starvation (**Figure 5**). Humans who consume a diet with 100 g protein (16.0 g nitrogen) excrete

Figure 5 The total quantity and various components of urinary nitrogen excretion during prolonged starvation when five men and five women volunteers were given water, salt, and vitamins. The nitrogen contents of urea, ammonium, creatinine, and uric acid are displayed. TUN, total urinary nitrogen.

15.5 g of nitrogen in the urine. Most of the nitrogen (85%) is excreted as urea. Ammonium, uric acid, and creatinine account for most of the remaining urinary nitrogen. Starvation initially induces an acute decrease in total nitrogen excretion. After 3–6 days of starvation, total urinary nitrogen decreases gradually, so that after 36 days of starvation the nitrogen excretion is 4.6 g d^{-1} . The biggest decrease is in the exponential decay in urea nitrogen excretion. The excretion of ammonium ion (NH_4^+) parallels the excretion of AcAc^- and $\beta\text{-OHB}^-$; it peaks at $120\text{--}140 \text{ mmol d}^{-1}$ at 6–9 days of starvation. After 15–18 days of drinking only water, NH_4^+ overtakes urea as the dominant urinary nitrogen compound. Urinary NH_4^+ gradually decreases as starvation is prolonged. NH_4^+ , AcAc^- , and $\beta\text{-OHB}^-$ urinary excretion rates are sensitive to small quantities of ingested glucose. In early studies of metabolism during starvation, subjects were allowed to drink beverages that contained carbohydrates. This distorted both urea and NH_4^+ urinary excretion. The excretion of creatinine decays in a linear manner that is dependent upon diminishing body muscle mass that occurs as starvation progresses. The output of uric acid in the urine drops acutely during the first 4 days of starvation as ketonuria rises. Thereafter uric acid nitrogen excretion plateaus at 2 mmol d^{-1} (120 mg d^{-1}).

The rate of urea excretion provided the first clue that the concept that brain metabolized only glucose for energy had to be modified. Research in the first half of the twentieth century established that for each gram of urinary nitrogen excreted, 3.5 g of glucose could be synthesized from amino acids. Excluding the glycerol that is present in triglycerides, only trivial quantities of glucose could be derived from triglyceride. The brain requires 100–125 g of glucose or equivalent energy sources daily. Plasma FFAs cannot pass the blood–brain barrier to provide a source of energy. In 1967, it was shown that AcAc^- and $\beta\text{-OHB}^-$ were the primary fuels for brain metabolism during starvation. Therefore, gluconeogenesis is clearly important during starvation, but the quantity of glucose formed is less than the quantity needed to provide energy for the brain. However, it should be pointed out that tissues such as the red blood cells, kidney medulla, and lens of the eye use anaerobic glycolysis as a source of energy. The lactate and pyruvate generated by these tissues are recycled to the liver for the production of glucose.

Fuel Consumption during Starvation

While the liver and kidney release glucose into the blood during starvation, only the liver makes a net contribution of ketone bodies. However, more urinary excretion of AcAc^- and $\beta\text{-OHB}^-$ occurs than is extracted across the renal vascular beds, suggesting that the kidneys synthesize some of the ketone bodies excreted in the urine. Ketonuria augments ammoniogenesis. The deamination of glutamine to form α -ketoglutarate generates two molecules of NH_4^+ , which are released into the tubular urine to maintain electroneutrality and acid–base balance. As mentioned above, the α -ketoglutarate produced in this process enters the TCA cycle via anaplerosis, and is subsequently converted to glucose that is released into the blood. The kidney can also convert lactate, pyruvate, other amino acids, and perhaps glycerol into glucose. Clearly, the kidney shares the role of glucose production with the liver, but the kidneys make a net contribution to blood only after several days of starvation.

Early in starvation, the small intestine may provide gluconeogenic amino acids to the splanchnic (portal) system, but by 3 days of fasting there is no readily detectable release of alanine or glutamine into the portal blood in fasting humans.

After 3 days of starvation, skeletal muscles derive 50% of their energy requirements from ketone bodies and, as fasting progresses, muscle preferentially extracts a small quantity of AcAc^- and may release $\beta\text{-OHB}^-$. At this time in starvation, FFA provides the great majority of fuels for muscle.

After an overnight fast, the brain derives its energy from glucose, consuming $100\text{--}125\text{ g d}^{-1}$. As starvation progresses, blood glucose concentration decreases, and the concentration of AcAc^- and $\beta\text{-OHB}^-$ increases, ketone bodies then become the major fuels for brain metabolism. These water-soluble fuels have access to neurons and can supply two-thirds of the total energy requirements during prolonged starvation.

Concluding Statement

Humans are capable of surviving long periods without food, but there are major limitations in this ability. Death occurs

when about one-half of lean body tissue is consumed to provide energy. Morbidly obese individuals that are subjected to prolonged starvation can deplete the structural proteins of vital organs and die with triglyceride remaining in their adipose tissue. The adaptations that permit humans to survive in the absence of food provide a fascinating look at the underlying biochemical adaptations to starvation.

Glossary

Agonists Natural or synthetic ligands that bind to the hormone-binding domain of the receptor and stimulate activity.

Antagonists Ligands that compete with the agonists for binding to the hormone-binding domain, but do not cause activation of the receptor.

Nuclear receptors Ligand-activated transcription factors characterized by conserved zinc-finger motifs in their DNA-binding domains and smaller conserved regions in the hormone-binding domain.

Phosphorylation A posttranslational modification of an amino acid in which a phosphate group is added by a kinase.

Sumoylation A posttranslational modification of an amino acid in which a SUMO protein is added via an enzymatic cascade to modify the function of the protein.

Ubiquitination A posttranslational modification of an amino acid in which one or more ubiquitin monomers are added by the E3 enzyme. Ubiquitin frequently acts as a signal targeting the protein for degradation by proteasomes.

Overview of Nuclear Receptor Ligands and Mechanism of Action

Figure 1 shows the structures of some of the ligands for members of the nuclear receptor family. Estradiol is the primary ligand for both estrogen receptors, estrogen receptor α (ER α) and ER β . Testosterone, which is closely related to estradiol, is one of the two major ligands for the androgen receptor (AR). The ligands for the thyroid hormone receptor (T3 and T4) and the vitamin D receptor (1,25(OH)₂D₃) are also shown. The five major classes of steroids are synthesized from pregnenolone, which is derived from cholesterol through the actions of the cholesterol side-chain cleavage enzyme (P450_{scc}). The synthesis of the hormones is complex, with a number of alternate pathways leading to the same hormone. Testosterone and estradiol are derived from 17 α -hydroxy pregnenolone. Testosterone, the major circulating androgen, is synthesized in the testes of males and in the ovaries of females. It is important for development of the male reproductive tract, fertility, and secondary male characteristics. Estradiol, the major circulating estrogen, is produced in the ovaries of females. Estradiol is important in the female reproductive tract, playing roles in breast and uterine development, fertility, and also in bone and other tissues. Progesterone is synthesized directly from pregnenolone, and the major site of synthesis in females is the ovary. Progesterone, acting through the progesterone receptor (PR), plays important roles in the breast and uterus and in the maintenance of pregnancy. Progesterone is a precursor of corticosterone and aldosterone, which are synthesized in the adrenal glands. The mineralocorticoid, aldosterone, is important for salt retention in the kidney. The glucocorticoid, cortisol, is produced in the adrenals from 17 α -hydroxy pregnenolone and is important for regulation of carbohydrate metabolism; it also plays a role in suppressing immune responses. The secosteroid, 1,25(OH)₂D₃, is derived from cholesterol through a ultraviolet-catalyzed reaction in the epidermis followed by sequential hydroxylations in the liver and kidney. The action of 1,25(OH)₂D₃ is

important for calcium homeostasis and also plays a role in the differentiation of a variety of tissues. Thyroid hormones are produced from tyrosines and iodide in the thyroid gland. Thyroid hormones have multiple actions in regulating metabolism, typically increasing oxidation rates. The hormones are transported through the blood to their sites of action.

Figure 2 depicts the general mechanism of action of nuclear receptors. The ligands are all lipophilic compounds, which enter the cells by passive diffusion. They bind to their cognate intracellular receptors located either in the cytoplasm or the nucleus. The receptors can be divided into two classes – those that do not bind DNA in the absence of hormone (Figure 2(a)) and those that can bind to DNA in the absence of hormone (Figure 2(b)). The regulation of their activities differs somewhat. Classical steroid receptors such as AR, glucocorticoid receptor (GR), PR, mineralocorticoid receptor (MR), and ER belong to the first class; they are maintained in an inactive conformation capable of ligand binding by a complex of chaperone proteins including hsp90 and p23. Whether these complexes are nuclear or cytoplasmic depends upon the receptor. Upon ligand binding during the genomic pathway, the receptor changes its conformation, no longer binding to heat-shock proteins, homodimerizes and, if the unliganded receptor is localized in the cytoplasm, translocates to the nucleus. There, the receptor binds to DNA containing specific sequences called hormone response elements (HREs) that are typically found in the 5' flanking region of target genes. However, some HREs are more than 10 kb upstream and others are found in the introns of target genes. The receptor recruits components of the basal transcription machinery, as well as proteins termed coactivators that perform a variety of functions including histone acetylation that enhance transcription. In addition, these receptors can mediate a rapid, nongenomic activation of signaling pathways as discussed later. Unlike the receptors for classical steroids, thyroid receptors (TRs) are not bound to heat-shock proteins in the absence of hormone and, instead, are bound to the DNA as a heterodimer with the retinoid X receptor (RXR),

Figure 1 Structure of steroid and thyroid hormones. Estradiol is the ligand for estrogen receptor, testosterone is the ligand for androgen receptor, T₃-3,5,3',5'-tetraiodo-L-thyronine, T₄-thyroxine are the ligands for thyroid receptor, and 1,25-dihydroxyvitamin D₃ is the ligand for the vitamin D receptor.

another member of the steroid/thyroid hormone receptor superfamily (**Figure 2(b)**). In the absence of ligand, TR binds corepressors, which, in turn, bind histone deacetylases resulting in lower levels of histone acetylation and repression of target gene transcription. Hormone binding releases corepressors and promotes binding of coactivators, resulting in increased transcription. Agonist-bound receptors also are known to repress transcription of some target genes although mechanisms for repression are less well defined.

The Steroid/Thyroid Hormone Receptor Superfamily

The steroid/thyroid receptors are the largest family of ligand-activated transcription factors. In addition to the well-characterized steroid, thyroid, retinoid, and vitamin D receptors, the family contains receptors for numerous lipophilic metabolites and xenobiotics. A number of receptor family members are referred to as orphan nuclear receptors. These receptors were not initially identified on the basis that known hormones were regulating their physiological actions through a ligand-binding process, but rather through their sequence similarities to the known receptors. Investigators searched for additional steroid receptors using the conserved regions determined to be common to nuclear receptors in DNA-screening approaches and grouped them based on phylogeny. Although some orphan receptors were later found to be regulated by a ligand binding, for instance, peroxisome proliferator-activator receptor can respond to fatty acid derivatives and certain prostaglandins in addition to an array of synthetic ligands, some orphan receptors such as estrogen-related receptor and TR2 (testes receptor) still have no known ligand. Thus, these orphan receptors may either work independent of ligand or the ligand(s) responsible for their regulation have yet to be discovered.

Receptor Structure

Despite some evolutionary and functional differences, the steroid receptor family members have many similarities especially in their structure. As shown in **Figure 3(a)**, there are multiple domains in the receptors, with all receptors containing domains A–E and only a subset containing the additional F domain.

The N terminus

The N terminus or the A/B domain of the receptor is the least conserved domain among the family members. This region is the most variable in length ranging from a few amino acids to more than 500. This region has an activation function, AF-1, which contributes to the transcriptional activity of the receptor through binding of coactivators. The position of this region within the N terminus differs among the receptors. AF-1 has been defined functionally by deletion analyses, but to date no common structural motifs have been identified in this region.

The DNA-binding domain

The DNA-binding domain (DBD), region C, is important for the binding of receptor to the DNA and is the most highly conserved domain. This region has two type-2 zinc-finger motifs, which are responsible for DNA recognition and dimerization. Each finger is composed of four cysteines that coordinate with one zinc atom. Amino acids in this region also participate in receptor dimerization.

The hinge region

Downstream of the DBD is the hinge region (D), which contains a nuclear localization signal. This is a short lysine-rich region, with a high homology to the simian virus 40 T-antigen nuclear localization signal. Additional functions of this region are receptor specific.

Figure 2 Mechanism of steroid (a) and thyroid (b) hormone action. The two classes are distinguished, in part, by whether they are associated with heat-shock proteins (a) like classical steroid receptors or are bound to DNA in the absence of hormone (b) like thyroid hormone receptor. Classical receptors (a) can bind hormone, dimerize, and translocate to the nucleus in the 'nuclear' pathway. In some cases, they also mediate a rapid activation of signaling pathways in the 'nongenomic' pathway. In both the classical, genomic pathway (a) and the thyroid receptor pathway (b), binding of the agonist causes dissociation of proteins that repress activity and promotes a conformation that induces recruitment of coactivators stimulating transcription of the target gene. SR, steroid receptor; HRE, hormone response element; GTF, general transcription factor; RXR, retinoid X receptor; TR, thyroid receptor; CoA, coactivator; CoR, corepressor; Hsp90, heat shock protein 90; TPR, tetratricopeptide; Src, Src tyrosine kinase; GF, growth factor; GFR, growth factor receptor.

The ligand-binding domain

The ligand-binding domain (E) is essential for the binding of ligand. The primary interaction site for the hsp complex is also in this domain. Also located in this region is the second activation function domain, AF-2, which is responsible for ligand-mediated transcription of target genes. The relative importance of AF-2 and AF-1 in inducing transcription is receptor- and cell-type specific. The structures of the hormone-binding domains

of several receptors have been determined using X-ray diffraction. The hormone-binding domain consists of a series of 12 α -helices. Binding of hormone causes a substantial conformational change in the receptor exposing AF-2 for interactions with coactivators. This domain also contains the strongest dimerization interface in most steroid receptors. The function of the F domain, located at the C terminus of some receptors such as the ER is not well defined.

Figure 3 Receptor structure and DNA binding elements. (a) Shows the common structural features of nuclear receptors using GR as an example. The A/B region contains the AF-1, a region important for transcriptional activation. C is the DNA-binding domain, the most conserved region in the nuclear receptors. D contains a nuclear localization sequence. E contains the hormone-binding domain and second activation function AF-2. Some receptors also contain a C-terminal extension, termed the F domain, whose physiological function is not well described. (b) Shows sequences of consensus hormone response elements. The consensus sequence for a GRE (binds GR, AR, PR) and an ERE (binds ER) are shown. Vitamin D receptor and the thyroid hormone receptors bind to direct repeats separated by three and four nucleotides, respectively. Other receptors bind to direct or inverted repeats with a spacing of 0–6 (n_x indicates that the half-site may be separated by 0–6 nucleotides). GRE, glucocorticoid response element; ERE, estrogen response element; VDRE, vitamin D response element; TRE, thyroid response element; GR, glucocorticoid receptor; AF, activation function.

Receptor Binding to DNA

All of the classical receptors bind to their cognate HREs as dimers. The consensus binding sequence for AR, PR, GR, and MR, shown in **Figure 3(b)**, contains two half-sites separated by three nucleotides with the sites oriented to form a palindrome. ER recognizes a related pair of half-sites with the same spacing and orientation. Each monomer binds to a half-site. The class-II receptors, including vitamin D receptor (VDR) and TR, bind to pairs of half-sites whose sequences are identical to the ER half-site, but whose orientation (direct or inverted repeats) and spacing (0–6 nucleotides) determine the specificity of binding. TR and VDR each heterodimerize with RXR and bind to the 3' end (half of the HRE), whereas RXR binds to the 5' end (half of the response element). Although these sequences represent the consensus binding sites, natural sequences may differ significantly and promoters may contain combinations of HREs as well as individual half-sites all of which contribute to the final activity.

Steroid Receptor Coregulators

When the receptor binds to the DNA, it recruits a series of protein complexes that facilitate recruitment of proteins required for basal transcription of the receptors. Receptors bind proteins or protein complexes that modulate receptor activity through alterations in chromatin structure; these are termed coactivators and corepressors. Coactivators are defined as proteins that interact with the receptors and increase their ability to transactivate the target gene. The mechanism by which

individual coactivators achieve this can vary. More than 100 candidate coactivators have been identified. Although some coactivators function only with steroid receptors and a small subset of other transcription factors, others are used by many transcription factors. The best characterized of the steroid receptor coactivators (SRCs) is the p160 family of coactivators: SRC-1, SRC-2 (GRIP1, TIF2), and SRC-3 (Rac3, AIB1). These bind to the receptor recruiting additional coactivators, including cAMP response element binding (CREB)-binding protein (CBP), CBP-associated factor (p/CAF), and coactivator-associated arginine methyltransferase (CARM-1). CBP/p300, p/CAF and some of the p160 proteins are histone acetyl transferases and their binding increases local histone acetylation. Other coactivators include the DRIP/TRAP (D receptor interacting protein/thyroid hormone receptor-associated protein) complex. Many coactivators interact with AF-2 located in the ligand-binding domain (LBD). In other cases, coactivators interact with the AF-1 region and some interact with both domains. Interactions with AF-2 are typically mediated by LXXLL (L=leucine and X=any amino acid) motifs in the coactivator.

Another class of proteins, termed corepressor, reduces the activation of target gene transcription through interaction with the receptors. The best-characterized nuclear receptor corepressors are nuclear receptor corepressor (NcoR) and silencing mediator of retinoid and thyroid receptors (SMRTs). These proteins bind histone deacetylase complexes and also interact with class II receptors in the absence of hormone resulting in local reductions in histone acetylation. Corepressors do not bind to unliganded steroid receptors. However, steroid receptor antagonists cause changes in the conformation of the hormone-binding domain that induce binding of the corepressors.

Steroid Receptor Agonists and Antagonists

Although steroid receptor family members are important for normal physiological processes, there are a number of instances in which it is desirable to block the actions of selected steroid receptors. These include breast cancer (ER) and prostate cancer (AR). Thus, although natural antagonists of steroid receptor action have not been identified, much effort has been devoted to identifying compounds that will antagonize hormone action. These compounds compete with the natural ligand for binding to the hormone-binding domain of the receptors. Although some antagonists block dissociation from heat-shock protein complexes or destabilize the receptor, most of the antagonists promote dissociation from heat-shock proteins and cause the receptors to bind to DNA. However, the conformation induced by the antagonist differs from that induced by agonist. This prevents recruitment of coactivators to AF-2 and, instead, promotes recruitment of corepressors. In some cases, it is desirable to maintain the activity of a receptor in some tissues while inhibiting activity in other tissues. The most common example of this is the need for tissue-specific regulation of ER activity. Estradiol is important for maintaining bone mass and postmenopausal women frequently develop osteoporosis. However, estradiol can promote uterine cancer and may also be detrimental in breast. Thus, a great deal of effort has been devoted to developing selective estrogen receptor modulators (SERMs) which have tissue-specific agonistic and antagonistic activities.

Tamoxifen (a SERM) has been used in the treatment of breast cancer, but increases the risk of uterine cancer. A newer SERM, raloxifene, is an antagonist in both breast and uterus, but acts as an agonist in bone.

Cross-Talk between Nuclear Receptors and Cell Signaling Pathways

Phosphorylation and other Posttranslational Modifications of Receptors and Coactivators

The nuclear receptors and their coactivators are phosphoproteins; in some cases, enhanced cell signaling is sufficient to induce the transcriptional activity of the receptor in the absence of normal levels of ligand. The ability to be activated by cell-signaling pathways alone is receptor specific, although changes in cell signaling modulate the activity of all of the receptors. Estrogen receptors are activated both by growth factor pathways and by activation of protein kinase A. Other receptors such as GR, require hormone for activity. Recent studies show that there are many mechanisms to regulate receptor activity through posttranslational modification. Examples of posttranslational modification include phosphorylation, sumoylation, and ubiquitination. Phosphorylation of steroid receptors on Ser, Thr, and Tyr residues can occur in the absence of ligand or can be induced by ligand binding and/or kinase signaling to regulate various functions, including protein stability, hormone sensitivity, DNA binding, subcellular localization, and protein interactions. Lysine residues can be modified by ubiquitination, sumoylation, or acetylation and can regulate protein turnover, subcellular localization, DNA-binding, transcriptional potential, or affect chromatin structure that controls the availability of promoter regions to regulatory proteins. Posttranslational modifications of coactivators are also important for regulation of receptor-specific functions.

Functional Interactions between Nuclear Receptors and Signal-Regulated Transcription Factors

In addition to altering transcription through direct binding to DNA, nuclear receptors alter transcription through interactions with other transcription factors. In some cases, these protein-protein interactions enhance transcription, while in others they prevent binding of the transcription factor to its DNA target site in a process referred to as transrepression. For instance, GR can interact with additional transcription factors in order to prevent these proteins from binding to and activating their respective targets. This type of process has been shown to be important for the antiinflammatory actions of GR. In other cases, the receptor binds to the factors on their DNA target sites influencing (either + or –) the transcription of a target gene. GR also can inhibit the transcription of certain genes by direct binding to negative GREs in the promoter regions of these genes. **Figure 4** shows the comparison between two of these pathways for ER. In the upper panel is the classical DNA-binding-dependent induction of transcription. We next depict the ability of ER to induce transcription through interactions with AP-1 complexes. In this instance, both estradiol as well as SERMs will stimulate the activity of AP-1.

Figure 4 Mechanisms of transcription activation by nuclear receptors. (a) Shows the classical pathway for transcriptional activation with a steroid receptor dimer binding directly to a hormone response element. (b) Shows an alternative mode of activation. In this case, a receptor such as the estrogen receptor binds to another transcription factor in a process referred to as tethering and influences transcription through its interactions with the transcription factor and the recruitment of coregulator proteins to the complex. ER, estrogen receptor; AP-1 RE, AP-1 response element; ERE, estrogen response element.

Nuclear Receptor Stimulation of Cell-Signaling Pathways

Both of the pathways above can be considered genomic pathways in that the nuclear receptor acts by directly altering transcription. Nuclear receptors can also act through stimulating kinase activity, although the final downstream target may be a change in transcription. These actions are rapid (minutes) and are termed nongenomic (**Figure 2**). This process is thought to occur close to the cell membrane and involves the cross-talk of steroid receptors with various adaptor proteins, G proteins, and receptor tyrosine kinases. There is evidence that activation of nuclear receptors can lead to downstream activation of mitogen-activated protein kinase. In some cases, this is through activation of Src kinase and in others through generation of a ligand for a growth factor receptor. There are numerous other examples of these rapid actions. Induction by estradiol of nitric oxide synthase activity in endothelial cells is a rapid response that does not require transcription. Thus, steroid/thyroid hormones alter cellular activities through multiple mechanisms.

Glossary

dOrai/*Drosophila* Orai The *Drosophila melanogaster* homolog of ORAI proteins. dOrai subunits oligomerize to form the pore domain of the calcium-release activated calcium (CRAC) channels in *Drosophila melanogaster*.

dStim/*Drosophila* Stim The *D. melanogaster* homolog of STIM proteins. dStim is the endoplasmic reticulum (ER) membrane resident protein that senses decreased ER calcium levels, oligomerizes and translocates toward the plasma membrane (PM) where it physically interacts with and activates dOrai. Together, dOrai and dStim form the CRAC channel in *D. melanogaster*.

ORAI ORAI molecules, named after the three keepers of the gates of heaven in Greek mythology, are conserved transmembrane proteins that form the pore of the CRAC channels. 'ORAI' is used to describe ORAI homologs from any species.

Orai1/Orai2/Orai3 The three mammalian homologs of ORAI proteins. Orai1 subunits oligomerize to form the pore domain of the CRAC channels in mammalian T cells. The three homologs are expressed in other tissues as well.

STIM Stromal interaction molecule, STIM, is a conserved endoplasmic reticulum (ER) membrane resident protein that senses decreased ER calcium levels, oligomerizes and translocates toward the PM where it physically interacts with and activates ORAI oligomers. Together, ORAI and STIM proteins form the CRAC channel. 'STIM' is used to describe STIM homologs from any species.

STIM1/STIM2 The two mammalian homologs of STIM proteins. STIM1 and STIM2 are ER membrane resident proteins that sense decreased ER calcium levels, oligomerize and translocate toward the PM where they physically interact with and activate Orai1/Orai2/Orai3. Together, STIM and ORAI proteins form the CRAC channel.

Introduction

Calcium ions (Ca^{2+}) are vital for cell function. Muscle contraction, synaptic transmission, and exocytosis are just a few examples of physiological processes that cannot occur without Ca^{2+} . Disruption of Ca^{2+} homeostasis can cause apoptosis and cell death. As a second messenger, Ca^{2+} also drives gene expression in many cell types. In lymphocytes, for instance, a sustained increase of cytosolic Ca^{2+} concentration ($[\text{Ca}^{2+}]_i$) is required for cytokine production and cell proliferation through the nuclear factor of activated T cells (NF-AT) transcription factor pathway. Under physiological conditions, receptor stimulation (T-cell receptor (TCR) in T cells, fragment, crystallizable region, receptor (FcR) in mast cells, etc.) induces a cascade of biochemical reactions which result in the production of inositol-1,4,5-trisphosphate (IP_3) by phospholipase C. IP_3 then binds to its receptor in the endoplasmic reticulum (ER) membrane and causes Ca^{2+} release from the ER into the cytosol. But the limited amount of Ca^{2+} contained in the ER allows only a small increase in $[\text{Ca}^{2+}]_i$ that lasts just a few minutes. Ca^{2+} release from the ER is not sufficient for activation. A mechanism for cytosolic Ca^{2+} influx is, therefore, required for a sustained and productive Ca^{2+} signal following receptor engagement.

In 1986, James Putney proposed that depletion of the ER Ca^{2+} store may initiate Ca^{2+} influx across the plasma membrane (PM) in nonexcitable cells through a mechanism called capacitative Ca^{2+} entry or store-operated Ca^{2+} entry (SOCE). Patch-clamp experiments in Jurkat T cells and mast cells, subsequently, revealed a tiny Ca^{2+} -selective current that indeed was activated in response to ER Ca^{2+} store depletion. In experiments, this same current was evoked by six distinct experimental maneuvers that have as their common denominator a

reduction in ER luminal Ca^{2+} concentration: (1) the physiological immunoreceptor stimulus that generates IP_3 , causing Ca^{2+} release through IP_3 receptor channels in the ER membrane; (2) addition of IP_3 to the pipette internal solution to open IP_3 receptor channels; (3) application of Ca^{2+} ionophores such as ionomycin that transport Ca^{2+} across membranes and thereby cause Ca^{2+} release; (4) passive store depletion by dialysis of the cell with Ca^{2+} chelators from the patch pipette (this lowers ER Ca^{2+} gradually as Ca^{2+} leaks from the ER into the cytosol and is then buffered); (5) loading of Ca^{2+} chelators into the ER lumen to reduce the intraluminal-free Ca^{2+} concentration; and (6) application of sarco/ER Ca^{2+} adenosine triphosphatase (SERCA) pump inhibitors such as thapsigargin to reduce intraluminal Ca^{2+} by blocking reuptake into the ER. As the release of Ca^{2+} from the ER store is necessary and sufficient for current activation, this tiny Ca^{2+} current was named Ca^{2+} release-activated Ca^{2+} (CRAC) current. Thus, unlike in excitable cells where Ca^{2+} enters mostly through voltage-gated Ca^{2+} channels or ligand-gated Ca^{2+} channels, in nonexcitable cells and particularly in immune cells the main Ca^{2+} influx pathway is store-operated and mediated by CRAC channels.

The biophysical properties of the CRAC current are well defined. The channel is gated by ER Ca^{2+} store depletion *per se* and carries an inwardly rectifying and highly Ca^{2+} -selective ($P_{\text{Ca}}/P_{\text{Na}} > 1000$) current. Like voltage-gated Ca^{2+} channels, CRAC channels conduct Na^+ only in the complete absence of divalent cations but do not conduct monovalent cations the size of Cs^+ or larger, placing a limit on the pore size of about 3.5 Å. Consistent with the small pore diameter, the single channel conductance is extremely low (21 fS in 20-mM Ca^{2+}). In addition to Ca^{2+} , the channel is able to conduct other divalent cations such as Ba^{2+} or Sr^{2+} , but not Mg^{2+} .

Ca^{2+} influx results in rapid inactivation of the CRAC current (in mammalian but not *Drosophila* cells). This biophysical fingerprint was developed from the late 1980s through the 1990s, but the underlying molecular constituents and the activation mechanism were only recently illuminated. It took much longer than the molecular identification of many channels because two essential components are required. STIM proteins provide the mechanistic link between ER Ca^{2+} store depletion and the PM; and ORAI proteins form the Ca^{2+} -selective pore of the CRAC channel.

What about the transient receptor potential (TRP) channel family, members of which were once among the leading candidates to form the CRAC channel? The biophysical properties of TRP channels vary widely in their gating and cation-selectivity characteristics. Several members of the canonical TRP (TRPC) channel subfamily are activated by signaling pathways that cause Ca^{2+} release from the ER. However, these same signaling pathways also generate messengers such as diacylglycerol which on its own activates some TRPC channels. The diverse-gating characteristics of TRP channels resulted in uncertainty regarding their ability to respond to ER Ca^{2+} store depletion. Moreover, compared to CRAC channels formed from ORAI subunits, TRPC channels are less selective for Ca^{2+} , allowing a significant component of Na^+ current. The discovery of STIM proteins has allowed researchers to test the hypothesis of STIM involvement in TRPC channel activation, and while some data suggest STIM-mediated activation of TRPC channels, it remains controversial.

Identification of STIM and Orai Proteins

In 2005, results of RNA-interference (RNAi) screens revealed STIM proteins as an essential component of the CRAC channel activation mechanism. An initial RNAi candidate screen in *Drosophila* S2 cells sought to identify molecules responsible for thapsigargin-induced Ca^{2+} entry, an experimental way to activate SOCE in intact cells without involving receptor engagement that could trigger potentially irrelevant proximal signaling pathways. Hits were defined by an apparent decrease in SOCE as a result of RNAi treatment for a set of selected genes. *Drosophila* Stim (dStim) was the only hit in this screen; the mammalian homolog STIM1 was then shown to be required for SOCE in T lymphocytes and other human cells. *Drosophila melanogaster* and *Caenorhabditis elegans* have only one Stim protein, whereas two homologs are present in vertebrate genomes: STIM1 and STIM2. An independently conducted RNAi screen identified both STIM1 and STIM2 for SOCE in human HeLa cells. STIM1 had been formerly identified as a molecule required for interaction of pre-B cells with bone marrow stromal cells and given the name stromal interacting molecule, later transformed to 'STIM'. It had also been implicated in tumor suppression. The essential role of dStim in *Drosophila* cells and STIM1 in human cells in mediating SOCE and CRAC current was unambiguously evidenced by Ca^{2+} imaging and whole-cell recording.

STIM proteins are essential mediators of SOCE, but they do not make up the ion-conducting pore of the CRAC channel. Following the success of the candidate-screening approach that

correctly identified a requirement for STIM proteins, the search for the CRAC channel continued by extending RNAi screening to the complete genome of *Drosophila* S2 cells. In 2006, three independent genome-wide screens led to the identification of the previously unheralded *Orai* (formerly known as *olf186-F*, renamed *Orai* and also known as *CRACM*). Only one *Orai* gene is found in the *Drosophila* genome (dOrai), but three mammalian homologs exist: Orai1, Orai2, and Orai3.

The mechanistic roles of STIM and ORAI as the two essential molecular components underlying the CRAC current were clarified by key overexpression and mutagenesis studies. Coexpression of dStim and dOrai, or STIM1 and Orai1, amplified the CRAC current to extremely high levels of functional expression. These studies suggested a requirement for both proteins and nothing else. Mutagenesis of STIM demonstrated its ER Ca^{2+} sensor and messenger functions that trigger signaling from the ER to the PM to activate Ca^{2+} influx. Mutagenesis of ORAI demonstrated its pore-forming function. In addition to activating Ca^{2+} -selective Orai1 channels, available evidence indicates that STIM1 can also activate several Ca^{2+} -permeable TRPC channels to cause SOCE. How does STIM1 convey information regarding ER Ca^{2+} store depletion to its PM partners? Briefly, once the ER luminal Ca^{2+} concentration drops, STIM physically translocates from the bulk ER to specialized junctions at the PM where it interacts directly with ORAI or TRPC subunits and activates channel activity, resulting in SOCE. In this article, we discuss each step of this signaling mechanism.

STIM Localization and Structural Domains

STIM proteins are found in both ER and PMs. However, the ER-resident STIM protein population is predominant and is the one implicated in SOCE. STIM proteins are highly conserved type I membrane proteins, with N-terminal and cytosolic C-terminal domains flanking a single transmembrane segment (Figure 1). The N-terminus in the ER lumen is composed of a signal peptide sequence, two EF-hand domains (one of which is responsible for binding and, thus, sensing ER Ca^{2+}), and a glycosylated sterile α motif (SAM) protein-protein interaction domain. A nuclear magnetic resonance structure of the EF-hand and SAM domains of STIM1 elucidates the Ca^{2+} -binding site of the canonical EF hand 1 that triggers signaling from the ER to the PM following Ca^{2+} store depletion. Adjacent to the hydrophobic membrane-spanning sequence, a cytosolic ezrin-radixin-moesin domain encompasses two coiled-coil domains. The proximal coiled-coil appears to mediate dimerization of STIM under resting conditions. The distal coiled-coil domain plays a key role in activating current through ORAI channels in the PM, functioning as a CRAC-activating domain (CAD). A shorter inactivation domain of STIM1, found directly downstream of the distal coiled coil, is involved in fast Ca^{2+} -dependent inactivation. The more distal STIM C-termini vary among classes of organisms. Invertebrate STIM proteins lack the serine/proline- and lysine-rich domains that may help to anchor STIM1 to negatively charged phospholipids in the PM following Ca^{2+} store depletion.

Figure 1 Functional domains of *Drosophila* Stim and mammalian STIM1 and STIM2. STIM proteins implicated in store-operated calcium entry reside in the ER membrane. *Drosophila* Stim has a longer N-terminus, and shorter C-terminus, than the mammalian homologs STIM1 and STIM2. The N-termini of all STIM proteins include a single signal peptide domain, two EF-hand domains and a sterile α motif (SAM) domain. Of the two EF hands, the canonical EF1 (cEF1) domain binds Ca^{2+} (●) when ER stores are filled, and releases Ca^{2+} upon ER store depletion. N-linked glycosylation sites within the SAM domain are indicated as ⋈. Just downstream of the single transmembrane domain is found a conserved ezrin–radixin–moesin (ERM) domain made up of two coiled-coil (CC) domains: a proximal domain that mediates dimerization and a more distal domain that contains a CRAC-activating domain (CAD, overlapping with segments defined by other groups and designated OASF, Orai-activating Stim fragment; CCb9, coiled-coil domain-containing region b9; and SOAR, Stim Orai-activating region). Recent studies on STIM1 have also demonstrated an inactivation domain (■) following the coiled-coil domains. The downstream domains of the STIM C-termini vary; only mammalian homologs contain proline/serine- and lysine-rich domains. Functionally significant sites of posttranslational modification are indicated by ball and stick moieties: a conserved cysteine modification (S-glutathionylation of C56) and two STIM1-specific phosphorylation sites (S486 and S668).

STIM Proteins as ER Calcium Sensors

Ca^{2+} unbinding from STIM is the molecular switch that triggers SOCE following depletion of the ER Ca^{2+} store. The presence of an N-terminal EF-hand domain suggested a possible function of STIM proteins in sensing changes in ER luminal Ca^{2+} concentration. In fact, when the EF hand of STIM1 was mutated in such a way as to prevent it from binding Ca^{2+} , the CRAC channel was shown to become activated as cells exhibited constitutive Ca^{2+} influx, bypassing the normal requirement for ER Ca^{2+} store depletion to activate the CRAC channel. The ER luminal Ca^{2+} concentration in a resting cell is $>400 \mu\text{M}$, orders of magnitude larger than the cytosolic Ca^{2+} concentration of $\sim 50 \text{ nM}$. The Ca^{2+} concentration gradient across the ER membrane is maintained by continuous activity of the SERCA pump. Experimental data showed that an isolated EF hand-SAM truncation of STIM1 binds Ca^{2+} in a 1:1 ratio, with a dissociation constant in the hundreds of micromolar range. Moreover, measuring the luminal ER Ca^{2+} concentration simultaneously with CRAC current demonstrated a steep relationship (Hill coefficient of 4) between ER Ca^{2+} concentration and PM Ca^{2+} channel activity, which is

initiated when luminal Ca^{2+} falls below $400 \mu\text{M}$. The EF hand of STIM1 binds Ca^{2+} with low affinity when ER Ca^{2+} stores are full and releases Ca^{2+} following ER store depletion, leading through several further steps to Ca^{2+} influx across the PM.

STIM Oligomerization: Signal Initiated

Conformational changes in the EF-SAM domain trigger STIM signaling following Ca^{2+} store depletion. Under resting cellular conditions, STIM proteins form dimers that are stabilized by interactions between the membrane-proximal coiled-coil domains. Upon ER Ca^{2+} store depletion, STIM dimers oligomerize; this step is mediated by the N-terminal SAM domains adjacent to the EF-hands that trigger conformational changes when Ca^{2+} unbinds. Notably, chemically induced oligomerization at the N-termini of chimeric STIM1 proteins suffices to send STIM1 to the PM and to activate CRAC current, independent of ER Ca^{2+} store depletion. STIM oligomerization is, thus, a crucial step in CRAC channel activation, causing STIM1 translocation to ER–PM junctions where the ER membrane and PM are closely apposed.

STIM Translocation to the PM: Signal Transmitted

STIM itself senses and then relays the message of ER store depletion directly to PM-resident ORAI channels. Following ER Ca^{2+} store depletion, STIM proteins oligomerize and translocate while still embedded in the ER membrane, forming clusters known as 'puncta' at junctions that are closely apposed to the PM. Both native and fluorescently tagged STIM proteins were shown to migrate to the PM only following Ca^{2+} store depletion. However, mutant Stim or STIM1 proteins lacking the ability to bind Ca^{2+} not only caused constitutive activation of CRAC channels but also were shown to be translocated to the PM even though ER Ca^{2+} stores remained filled. These key studies validated the ER Ca^{2+} sensing and messenger functions of STIM. Förster resonance energy transfer microscopy and electron microscopy have revealed that STIM1 migrates close enough to the PM (within 20 nm) to contact ORAI channel-forming subunits directly. In small cells, oligomerization and translocation of STIM molecules requires 10–30 s following ER Ca^{2+} store depletion and is reversible upon refilling of the ER Ca^{2+} store. There is still much to learn about the subcellular pathway by which STIM proteins migrate from the bulk ER toward the PM as Ca^{2+} -unbound oligomers and back again when the ER Ca^{2+} store is refilled. The ER structure does not appear to change dramatically following store depletion, yet STIM1 migrates directionally and reversibly from bulk ER to predefined junctions with the PM when Ca^{2+} stores are depleted. STIM1 binds to EB-1 at the growing plus end of microtubules, but the role of microtubules in localization and transport of STIM1 to ER–PM junctions needs to be clarified.

STIM Signal Turned On or Off by Posttranslational Modification

Reactive oxygen species (ROS) have long been implicated in aberrant Ca^{2+} signaling through a variety of mechanisms. In addition to Ca^{2+} sensing, STIM proteins may function as cellular redox sensors to initiate Ca^{2+} influx under conditions of oxidative stress induced by ROS. A recent study indicates that the STIM signal from ER to the PM can be turned 'on' by posttranslational modification initiated by cellular oxidants at a conserved cysteine residue (C56 in human STIM1) close to the Ca^{2+} -sensing EF hand of STIM1. A covalent S-glutathionylation reaction at this residue appears to reduce the Ca^{2+} affinity of the adjacent EF hand, resulting in constitutive activation of Ca^{2+} influx through CRAC channels. Moreover, mutation of C56 to alanine replicates the store-independent Ca^{2+} phenotype, highlighting the importance of this residue for Ca^{2+} sensing. Constitutive activation of the STIM1-signaling mechanism may constitute an important and potentially dangerous mechanism by which STIM1 posttranslational modification under conditions of oxidative stress can lead to inappropriate Ca^{2+} signals that result in mitochondrial overload and cell death.

In contrast, the STIM signal can be turned 'off' by a very different posttranslational modification. STIM1 has numerous sites of phosphorylation by serine–threonine kinases; some of these play a role in the previously documented cell-cycle dependence of CRAC channel activity. During M phase, when

cells are rounded up and dividing, the usual experimental measures to deplete the ER Ca^{2+} store fail to activate CRAC current. Suppression is due to phosphorylation during mitosis of STIM1 at two key serine residues (S486 adjacent to CAD and S668 near the poly-lysine C-terminus in human STIM1), resulting in a failure of STIM1 to translocate to the membrane. This uncoupling of ER Ca^{2+} store depletion and SOCE could result from inhibition of STIM1 oligomerization or interference with undetermined molecular interactions that help guide STIM1 to ER–PM junctions.

STIM-Mediated Channel Clustering and Subunit Organization: Signal Received

How does STIM trigger SOC channel activation, and how is the signal modulated and turned off? In addition to serving as the ER Ca^{2+} sensor and the messenger to the PM, STIM organizes ORAI or TRPC subunits into mirror-image molecular clusters at ER–PM junctions and activates Ca^{2+} influx. The newly formed coclusters of messenger STIM and corresponding ORAI channel proteins colocalize precisely with sites of Ca^{2+} influx. This induced aggregation of ORAI (or TRPC) channels concentrates local Ca^{2+} signaling at the particular regions of the cell where activator STIM molecules and ORAI channels cocluster. In T cells, this takes place at the immunological synapse formed with the antigen-presenting cell (APC). Engagement of TCRs at the leading edge of a T cell with antigen bound to major histocompatibility complex on the APC initiates signaling that leads to IP_3 generation and Ca^{2+} release from the ER. Following ER Ca^{2+} store depletion STIM1 translocates preferentially to the immune synapse (some also distributes in caps at the rear end of the cell), and concentrates Orai1 locally such that Ca^{2+} influx into the T cell is maximal immediately adjacent to the synapse. Thus, in at least this circumstance, STIM1 promotes Ca^{2+} influx in a highly specialized subcellular-signaling platform where kinases, adapter proteins, K^+ channels, and other signaling molecules are also concentrated.

At the molecular level, the CAD domain of STIM1 binds directly to the Orai1 protein. STIM1 plays a dual role in Orai1 channel activation, promoting subunit assembly into tetramers and inducing a conformational change in the Orai1 tetramer that opens the Ca^{2+} -selective pore. The functional unit of the CRAC channel is unambiguously a tetramer of dOrai (or Orai1) subunits, but there is disagreement about the state of dOrai (dimers) and Orai1 (tetramers) in resting cells. Available evidence points to a stoichiometry of two STIM1 molecules per tetramer of Orai1 in the active state. STIM-mediated dimerization of ORAI dimers is a unique mechanism of channel subunit assembly mediated by the activator protein.

Opening ORAI: Signal Delivered

How exactly does STIM binding open ORAI tetramers? Abundant evidence indicates that the cytosolic C-terminus of STIM1 functions as the effector domain to open ORAI through a physical electrostatic interaction between the C-terminal distal coiled-coil domain of STIM1 and the coiled-coil domains present in the cytosolic C-termini of ORAI proteins. Indeed, the

Figure 2 STIM1 translocates to ER–PM junctions to interact with Orai1 and activate SOCE after ER Ca^{2+} store depletion. Background shading indicates Ca^{2+} concentrations from ~ 100 nM in cytosol (light blue) to 2 mM extracellular (dark blue). Under resting conditions (left), Ca^{2+} (●) is bound to the EF hand of STIM1 (shown as a dimer) and Orai1 subunits (■, shown as dimers) are nonconducting. Inactivation domains are indicated for STIM1 (□) and Orai1 (yellow lines in the TM2–TM3 loop and a calmodulin-binding domain (CBD, ▢) adjacent to TM1). Following ER Ca^{2+} store depletion, Ca^{2+} unbinds from STIM, STIM proteins oligomerize and migrate to ER–PM junctions, and induce accumulation of ORAI channels as tetramers. One STIM dimer is shown binding to one ORAI tetramer to induce Ca^{2+} influx. Oligomeric STIM proteins are present at puncta and the binding stoichiometry may vary.

truncated C-terminal portion of STIM1 or dStim is sufficient, when expressed as a cytosolic protein, to constitutively activate native CRAC current, as well as overexpressed ORAI or TRPC channels, bypassing the normal requirement for Ca^{2+} store depletion. Recent studies have narrowed down the minimal activating sequence of STIM1 to approximately 100 amino acids spanning the distal coiled-coil domain. Known by several acronyms and here termed the CAD; overlapping with fragments termed SOAR, OASF or CCb9; see Figure 2), this fragment of STIM1 was shown to activate the Orai1 current and to bind directly to both the N- and C- termini of purified Orai1 protein. Positively charged residues within CAD likely interact with negatively charged ones in the C-terminus of Orai1 as an essential aspect of channel gating. A recent study confirmed that only STIM and ORAI are required for channel activation, as recombinant STIM1 activates Ca^{2+} flux in yeast vesicles expressing human Orai1 in the absence of other proteins related to SOC channel function. However, the STIM–ORAI interaction may be modulated by other protein partners. For example, the EF-hand protein CRACR2A (CRAC regulator 2A) has been identified as a novel cytosolic Ca^{2+} sensor that forms a ternary complex with Orai1 and STIM1, stabilizing CRAC channels in T cells. Elucidating the exact molecular mechanism by which STIM activates ORAI (and TRPC) channels remains a challenging problem.

Inactivation and Store Refilling: Signal Dampened and Terminated

SOCE is normally terminated by the reuptake of Ca^{2+} into the ER, which may take a few minutes. However, on the

millisecond timescale, Ca^{2+} influx through the CRAC channel results in inactivation of CRAC current, thus providing fast and local negative feedback. Inactivation results in smaller, but not completely diminished, Ca^{2+} currents. Long before the molecular identity of the CRAC complex was known, researchers predicted the existence of a Ca^{2+} -binding site within nanometers of the PM that would bind Ca^{2+} and, thus, induce fast Ca^{2+} -dependent inactivation. Recent studies identified structural components of STIM1 and Orai1 that play a role in mediating fast inactivation. For one, an inactivation domain of STIM1 has been defined. Directly downstream of the CAD domain, a short stretch of STIM1 bears several negative charges that are required for fast, Ca^{2+} -dependent inactivation. Two intracellular parts of Orai1 have also become implicated. A cytosolic loop between the second and third transmembrane segments of Orai1 may occlude the intracellular side of the pore in order to inactivate CRAC current. Also, a calmodulin-binding domain at the N-terminal of Orai1, very close to the PM, binds calmodulin in the presence of Ca^{2+} . Perhaps incoming Ca^{2+} ions bind to this anchored calmodulin to initiate fast Ca^{2+} -dependent inactivation. The CRAC current completely subsides following refilling of the ER Ca^{2+} store, the breakdown of STIM1 puncta, and STIM1 moving out of the ER–PM junctions. This process may be accelerated when $[\text{Ca}^{2+}]_i$ is elevated.

STIM1 and TRPC Channels

The search for the molecular determinants of the CRAC channel took many years and several candidates were proposed, mostly the TRP channel family members. Moreover, the biophysical properties of store-operated current recorded in various cell

types were different. For example, unlike classical CRAC current in immune cells, the TRPC channels are relatively nonselective, have high single-channel conductance, and exhibit straighter current–voltage relationships. With the discovery of STIM1 as an ER Ca^{2+} sensor the problem started to resolve. Indeed, if STIM1 interacts with Orai1, can it also interact with TRPC channels? One group showed that STIM1 can activate TRPC1, C2, C3, C4, C5, and C6 (but not C7) via electrostatic interaction. Two conserved negatively charged aspartates of TRPC1 ($^{639}\text{DD}^{640}$) or TRPC3 ($^{697}\text{DD}^{698}$) interact with a positively charged lysines $^{684}\text{KK}^{685}$ located in the polybasic tail of STIM1 resulting in channel activation. Also, the interaction with STIM1 facilitates TRPC1 localization into lipid raft compartments of the PM, switching the receptor-operated mode of the channel to the store-operated one. Direct interaction of TRPC channels with Orai1 is widely discussed in the literature, although it remains unclear and requires further investigation.

STIM in Health and Disease

Genetic studies in knockout mice and human immunodeficiencies are providing new insights into the physiological importance of the STIM family of proteins. Suppression of STIM1 expression, and to a lesser extent STIM2, has devastating effects *in vivo*. *Stim1*^{−/−} mice perished *in utero* or soon after birth of respiratory failure, although early embryos appeared to develop normally. *Stim2*-deficient animals survived after birth but for only a short period of time of 4–5 weeks. The physiological importance of STIM1 and STIM2 for immune cells function has been extensively confirmed at the cellular level using cells isolated from mice lacking STIM1, STIM2, or both. In primary T cells, deletion of *Stim1* resulted in a profound reduction of SOCE, and CRAC currents were nearly abolished. This phenotype is less pronounced in *Stim2*-deficient T cells, yet effects on cytokine production were profound in both *Stim1*- and *Stim2*-knockout T cells. Mice with a T-cell-selective deletion of both *Stim1* and *Stim2* developed a lymphoproliferative disorder due to impaired function of regulatory T cells. Mast cells derived from *Stim1* knockout mice also display a reduced SOCE leading to a strong impairment of acute degranulation and cytokine production by these cells. In heterozygous *Stim1*^{+/-} mice anaphylactic responses were mildly reduced suggesting that the CRAC channel is essential for mast cell function *in vivo* and is a potential drug target for the treatment of asthma. A role of STIM1 in platelets relating to cerebrovascular function has also been described. Platelets from *Stim1*-deficient mice have a markedly reduced agonist-induced SOCE and their activation and aggregation was reduced. Of potential clinical significance, bone-marrow chimeric mice with *Stim1* deficiency in hematopoietic cells, including *Stim1*-deficient platelets, are significantly protected from arterial thrombosis and ischemic brain infarction but have only a mild bleeding time prolongation. On the other hand, mice expressing a constitutively active EF-hand mutant of STIM1 had macrothrombocytopenia and an associated bleeding disorder. STIM1 gain of function increased the resting basal intracellular Ca^{2+} levels in platelets causing premature platelet activation and bleeding. Finally, macrophages lacking STIM1 cannot activate FcγR-induced Ca^{2+} entry and phagocytosis. As a direct consequence, *Stim1* deficiency results in resistance to experimental immune thrombocytopenia

and anaphylaxis, autoimmune hemolytic anemia, and acute pneumonitis.

Consistent with the ubiquitous expression of STIM proteins and their involvement in a broad array of cellular processes, *Stim* gene knockouts in mice lead to phenotypic manifestations outside the immune system. Neonatal lethality in *Stim1*^{−/−} mice is associated with growth retardation and a severe skeletal myopathy with muscle that fatigues rapidly. Collectively, these studies show the instrumental role of the STIM-mediated Ca^{2+} signaling in T lymphocytes, mast cells, skeletal muscle, platelets, and macrophages for these cells to accomplish their function *in vivo*.

Valuable insights into STIM function in animal models have recently been extended to the characterization of an immune deficiency syndrome due to mutation of STIM1 identified in a human family showing how aberrant STIM-mediated SOCE can translate into human disorders. This first described human ‘STIM-opathy’ arises from a frameshift nonsense mutation in exon 3 of *Stim1* resulting in a premature STOP codon and termination of STIM1 protein. STIM1 protein is undetectable in these patients resulting in a complex syndrome of combined immunodeficiency with infections and autoimmunity associated with hepatosplenomegaly, hemolytic anemia, thrombocytopenia, and reduced numbers of regulatory T cells. In addition, patients exhibited muscular hypotonia and an enamel dentition defect, similar to patients with immunodeficiency due to mutations in Orai1 or mouse models lacking STIM1 or Orai1.

Conclusion

SOC channels formed of ORAI or TRPC subunits are activated by the Ca^{2+} -sensing STIM proteins. The major properties of STIM were discussed: ER Ca^{2+} sensing followed by oligomerization, translocation to the ER–PM junctions, organization of ORAI (or TRPC) channels into PM clusters, and activation of SOC channels. Besides molecular mechanisms of SOC channel activation, the physiological importance of STIM was highlighted: *Stim1* null mice die *in utero* and patients with mutation in human STIM1 resulting in premature STOP codon manifest the severe combined immunodeficiency syndrome and muscular and enamel dentition disorders. Finally, additional functions of STIM, not discussed here, have been identified recently, including the activation of adenylyl cyclase resulting in store-operated cyclic adenosine monophosphate production, ER remodeling through EB1 binding, and inhibition of voltage-gated Ca^{2+} channels. Despite rapid progress in the SOC channel field, several key mechanistic questions remain. How does STIM translocate to the PM? What causes ORAI clustering? How does STIM open both ORAI and TRPC channels? Moreover, of biomedical significance, is STIM1 involved in tumorigenesis, and will it be an effective drug target for immunosuppression? Over the past 5 years, the pace of research on STIM and ORAI proteins has been extremely rapid.

Structure and Regulation of Pyruvate Dehydrogenases

J L S Milne, National Institutes of Health, Bethesda, MD, USA

Published by Elsevier Inc.

Glossary

Allosteric regulation Modulation of enzymatic activity by noncovalent binding of a specific metabolite at a location other than the enzyme active site.

Cryo-electron microscopy Electron microscopic method to image at cryogenic temperatures frozen-hydrated and unstained molecules or macromolecular complexes. These entities often may not be amenable to analysis using X-ray crystallography or nuclear resonance spectroscopy. Projection views of molecules in the same orientation relative to the electron beam are averaged together; then, distinct projection views are computationally oriented and aligned to create a three-dimensional reconstruction.

Feedback inhibition A post-translational control mechanism in which the end product of a biochemical pathway accumulates and interacts with the regulatory control enzyme of the pathway to inhibit its activity.

Intermediary metabolism The enzyme-catalyzed reactions occurring within cells that are required to extract chemical

energy from nutrient molecules and use it to synthesize and assemble cellular components.

Nuclear magnetic resonance (NMR) Spectroscopic method to determine the three-dimensional structure of molecules, typically in suspension, by placing the sample in a strong magnetic field and using intermittent exposure to radiofrequency waves that cause absorption and emission of energy arising from changes in the spin states of the nuclei of atoms.

Oxidation Loss of electrons from an ion or molecule.

Prosthetic group A metal ion or other organic compound, other than amino acid residues that binds covalently to a protein and is essential for its biological function.

Reduction Gain of electron by an ion or molecule.

X-ray crystallography Determination of three-dimensional atomic structures by analysis of the X-ray diffraction patterns that result when X-rays pass through a well-ordered crystalline array of molecules.

Introduction

Pyruvate dehydrogenases (PDHs) represent a cornerstone in cellular energy metabolism, linking glycolysis and the metabolism of branched chain amino acids to the citric acid cycle and lipogenesis. They belong to the family of 2-oxo acid dehydrogenases, and catalyze the irreversible oxidative decarboxylation of pyruvate to yield acetyl-coenzyme A (CoA), CO₂, and a reducing equivalent NADH. Acetyl-CoA feeds into the citric acid cycle to produce adenosine triphosphate (ATP) and additional reducing equivalents, which are used to generate additional ATP when energy is required during oxidative phosphorylation. Alternatively, acetyl-CoA is used during the synthesis of fatty acids when fuel storage is possible. The requirement of both bacterial and eukaryotic cells to maintain appropriate energy balance to control the tremendous flux of carbon units through these pathways necessitates stringent regulation of PDH activity as fuel sources peak and wane. This is accomplished through small metabolites, through transcriptional regulation of constituent enzymes, and, in higher organisms, through associated kinases and phosphatases that regulate the phosphorylation state of the enzyme complex in a tissue-specific manner. X-ray crystallographic and nuclear magnetic resonance (NMR) analyses of individual subcomponents, combined with cryo-electron microscopy of the intact multienzyme complexes, have begun to yield new insights into the mechanism and regulation of these fascinating cellular machines.

Components of Pyruvate Dehydrogenases

PDHs are large complexes with sizes ranging from 4 to 10 MDa and diameters ranging from 300 to 500 Å. Each complex contains multiple copies of three essential enzymes – E1, E2, and E3 – organized into complexes with octahedral or icosahedral symmetry, depending upon the organism. Multiple cofactors are critical to its function: thiamin diphosphate (ThDP), CoA, flavin adenine dinucleotide (FAD), and nicotinamide adenine dinucleotide (NAD), which are derived from vitamins thiamin, pantothenate, riboflavin, and niacin, respectively, and lipoic acid, used to form a covalently linked prosthetic group. The hallmark of PDH is a mobile swinging arm domain that orchestrates substrate channeling of covalently bound reaction intermediates produced during the multistep reaction to couple the active sites of the E1, E2, and E3 enzymes. Such structural integration serves to enhance reaction rates of a complex reaction while minimizing undesirable side reactions with other cellular metabolites, such as free lipoic acid.

The PDH of *Bacillus stearothermophilus* is the simplest representative of the icosahedral PDHs that are found in Gram-positive bacteria and in the mitochondrion of eukaryotic cells. It contains 60 copies of E2, a dihydrolipoyl acetyltransferase of 46 kDa; 42–48 copies of E1, a ThDP-dependent pyruvate decarboxylase that is an $\alpha_2\beta_2$ heterotetramer of 154 kDa; and 6–12 copies of E3, a FAD-dependent dihydrolipoyl dehydrogenase that is a homodimer of 98 kDa. E2 is a multifunctional protein

that has three domains. At the two ends of the molecule are a C-terminal, 27-kDa catalytic domain, and an N-terminal, 9-kDa lipoyl-binding domain, with a lipoyl lysine prosthetic group protruding from the apex of a tight β -turn. Between these two domains is a 4 kDa peripheral subunit-binding domain to which E1 or E3 bind tightly and mutually exclusively at partially overlapping sites. The three domains are each separated by a stretch of amino acids that are thought to form flexible linkers. Sixty copies of the E2 enzyme self-associate through the catalytic domain to form the icosahedral core of the complex that is decorated on the periphery by E1 and E3 enzymes, randomly distributed on the surface of the complex (Figure 1(a)). PDHs of Gram-negative bacteria have an analogous architecture although they consist of an octahedral assembly of 24 E2 subunits that have three lipoyl domains and bind E1 and E3 enzymes, both of which are α_2 homodimers.

Mammalian icosahedral PDHs are more complicated than their bacterial counterparts. In addition to the E2 molecules, their core scaffold contains between 12 and 20 copies of

E3-binding protein (E3BP), a polypeptide that has ~40% sequence identity to E2 but lacks the active site histidine amino acid residue that is essential for acetyltransferase activity of E2. E3BP is present in at least one of every four copies of E2 in the pentameric face of the dodecahedron. The mammalian E1 is an $\alpha_2\beta_2$ tetramer as in the case of *B. stearothermophilus*. E1 and E3 of mammalian PDHs bind selectively to the peripheral subunit-binding domain of E2 or E3BP, with affinities ranging from ~20 to 40 nM, respectively, and at occupancy levels that are lower than those seen in *B. stearothermophilus*. Mammalian PDH complexes also have two N-terminal lipoyl domains in E2. The outermost lipoyl domain acts as the swinging arm while the innermost associates noncovalently with regulatory kinases and phosphatases. These latter enzymes are generally present in low copy numbers, and modulate PDH activity by reversible phosphorylation of the E1 enzyme at three distinct sites.

Reaction Mechanism of PDH

Extensive biochemical analysis and X-ray crystallographic and NMR imaging studies on the individual components of PDH provide a wealth of information about the elegant series of reactions, shown in Figure 1(b), that underlie the conversion of pyruvate to acetyl-CoA and NADH, and the regeneration of the enzyme complex for subsequent rounds of catalysis.

E1 Reaction

E1, the rate-limiting enzyme, has two chemically equivalent active sites. These function by a flip-flop mechanism in which the active sites interact with each other while simultaneously performing different steps in the sequence of reactions catalyzed by E1. Each active site contains a bound ThDP that is held in a deep cleft by specific interactions with amino acid residues on both the α - and β -subunits of E1 and by a Mg^{2+} ion which forms a bridge between the protein and the pyrophosphate region of ThDP. The cofactor is positioned into a 'V-conformation' that places the N4' amino group of the pyrimidine ring adjacent to the C2 proton of the thiazolium ring. A proton associated with N1 of ThDP is transferred to a conserved glutamate residue on E1, permitting the extraction of a proton from the acidic C2 carbon by N4 to generate a carbanion intermediate. This highly reactive anion performs a nucleophilic attack on the ketone C2 carbon of pyruvate to yield a α -lactyl-ThDP intermediate that releases carbon dioxide to produce enamine-ThDP. Reductive acetyl transfer then occurs between this intermediate and the lipoyl-lysine prosthetic group of E2. The lipoate S6 position is first protonated by a basic amino residue in the active site of E1. A second carbanion is subsequently generated and the acetyl group and two electrons are transferred to the swinging arm of E2 by nucleophilic attack of the enamine on the S8 position of the lipoate. Finally, transfer of a proton to the N4' atom of ThDP resets the E1 active site to enable further catalysis.

E2 Reaction

X-ray crystallographic analysis of the octahedral form of the E2 catalytic core domain indicates that each monomer is tightly

Figure 1 Components and reaction mechanism of pyruvate dehydrogenase (PDH). (a) Schematic model of the icosahedral PDH. One E2 catalytic trimer of the icosahedral inner core is highlighted with its cognate outer lipoyl domains (blue), and peripheral subunit-binding domains (green) bound to an E3 homodimer (top) or to an $\alpha_2\beta_2$ E1 heterotetramer (bottom). The atomic structures of the three E2 domains and the E3 homodimer are from *B. stearothermophilus*, while the E1 complex is from *Pseudomonas putida*. The green linker regions are unstructured. (b) Diagram of the reaction mechanism of a 2-oxo acid dehydrogenase multienzyme complex. R is CH_3 in the case of the PDHs; ThDP, thiamin diphosphate; Lip, lipoic acid. associated with two other subunits related by threefold rotational symmetry. Like chloramphenicol acetyltransferase, a trimeric enzyme, each active site of E2 is located in a long 30 Å channel formed at the subunit interface that has a central conserved His amino acid residue that acts as a general base and two entrances for substrates. CoASH, the reduced form of CoA, enters from the interior side of the complex during disruption of a salt bridge between an Asp/Asn dyad found in the ground state of the enzyme. The acetylated lipoyl group, transported ~50–100 Å from the active site of E1 by the swinging arm, enters from the external side of the inner E2 core. Rotation of the Asn side chain positions it to hydrogen-bond with the central His residue, increasing the nucleophilicity of the His N ϵ 2 atom, which draws the hydrogen atom from the reactive sulfur of CoA, positioned 3.2 Å away. This reactive group then attacks the reactive S8 atom of the acetyl substrate and the tetrahedral intermediate is stabilized by a single hydrogen bond donated by a hydroxyl group of an adjacent Ser residue. Rearrangement of this intermediate completes the *trans*-esterification reaction in which the –SH group of CoA replaces the S-acetyl group of E2 to form acetyl-CoA and the reduced lipoamide group, both of which exit the active site cleft. Rotation of the Asn side chain to its ground state position completes the cycle.

E3 Reaction

E3 promotes the transfer of two hydrogen atoms from the reduced lipoamide group of E2 to the FAD prosthetic group of E3, restoring the oxidized form of the lipoyl-lysine group of E2 and ultimately leading to the production of NADH and a free proton. Each E3 monomer has two active sites and four distinct domains: a FAD-binding domain, an NAD-binding domain, as well as central and interface domains. Each active site is formed at the junction of the two subunits with binding pockets for NAD and dihydrolipoamide located on opposite sides of a centrally located flavin, which binds to each chain in an extended conformation to intersect the channel. The redox center of the enzyme consists of a reactive intramolecular disulfide bridge that couples with the flavin rings. Upon dihydrolipoamide binding, the first reductive half reaction occurs whereby electrons are transferred from dihydrolipoamide to open the reactive disulfide bridge, permitting one of the cysteine residues to form a charge transfer complex with the flavin. This half reaction is initiated by abstracting a proton from the substrate by a conserved histidine residue that interacts directly with the bound flavin. The FADH₂ form of E3 is required for binding of NAD⁺, which orients so that its nicotinamide rings are closely juxtaposed with the isoalloxazine rings of the flavin. The second oxidative half reaction then occurs, in which the reduced FADH₂ group transfers a hydride ion to NAD⁺ giving rise to a free proton and NADH, which enters into the respiratory chain to generate ATP. The reactive disulfide bridge of E3 is also regenerated during this half reaction.

Lipoyl Domain in Substrate Channeling and Active Site Coupling

Lipoyl domains in PDH complexes are highly conserved, flattened β -barrel motifs that attach the lipoyl group to the N⁶

amino group of an E2 lysine residue located at the apex of a tight β turn. This architecture creates a long flexible arm, containing the hydrocarbon chains of lipoate and of the lysine residue, that further increases the reach of the linker swinging arm and facilitates entry into the active site channels of E1, E2, and E3. The latter two enzymes have low substrate specificity for lipoate, and are able to function catalytically using free lipoate or other lipoate derivatives. The activity of E1, in contrast, is more than four orders of magnitude higher in the presence of the lipoyl domain corresponding to its cognate E2 as compared with free lipoamide, lipoylated peptides derived from the lipoyl domain, or with lipoyl domains from other E2 species. The lipoyl domain must be tethered to the complex for this effect, resulting in high (millimolar range) local concentrations around the E2 core. Mapping of specific interactions between E1 and its cognate lipoyl domain of E2 using NMR analysis indicates that a significant number of amino acid residues in the lipoyl domain interact with E1, provided both from a prominent surface loop near the lipoyl lysine and amino acids that form the lipoyl lysine β turn residues adjacent to the prosthetic group. Mutation of these sites impairs the E1 reaction. Far fewer interactions occur between the lipoyl domain and E2 and E3. Stringent control of the E1 is an effective mechanism to promote substrate channeling, ensuring that the acyl transfer reaction occurs efficiently without interference from nonproductive substrates such as lipoate. Although there is less specificity in the interactions between E2 and the lipoyl domains, the amino acids on the surface of the lipoyl domain tend to be acidic, while those on the external face of the E2 catalytic domain trimer tend to have patches of basic residues. Thus, nonspecific electrostatic interactions may help guide the trajectory of the lipoyl domain to the active site of E2. Specific interaction of the lipoyl domain with regulatory kinases and phosphatases in eukaryotic cells is also critical for modulation of PDH activity (see below).

Regulation of the PDH

The critical role of PDH at a central branch point in cellular metabolism is reflected by the multiple layers of regulation, often combined in a highly cell-specific manner, that control the precise flux of carbon between pyruvate and acetyl-CoA in response to cellular bioenergetic and biosynthetic requirements. In both bacterial and eukaryotic cells, rapid modulation of PDH activity can be accomplished by small metabolites and ions interacting directly with the complex, while long-term regulation occurs by transcriptional control of one or more of the constituent enzymes. Tissue-specific modulation of the phosphorylation state of PDH complexes by kinases and phosphatases is a key mode of regulation in many eukaryotic cells, and is especially well characterized in mammalian cells. This type of regulation is absent in bacteria. The kinases and phosphatases are themselves subject to allosteric and transcriptional regulation.

Biological Significance of PDH Regulation

PDH regulation in mammals effectively integrates the intermediary metabolism of glucose, amino acids, and lipids under a variety of nutritional and physiological states. For example,

suppression of PDH activity occurs upon ingestion of a high-fat/low-carbohydrate diet or during starvation, which conserves precursor compounds (pyruvate, lactate, and alanine) that are used to synthesize glucose and which causes most body tissues to rely on fatty acids or ketones for fuel. This spares the limited glucose supply for preferential use by neuronal tissues including the brain. Conversely, muscle movement and increased cardiac output during exercise require activation of the PDH complex, as does fatty acid or sterol biosynthesis, which use acetyl-CoA as a substrate. Dysfunction of PDH has long been appreciated in maple syrup disease, lactic acidosis, and primary biliary cirrhosis as well as, more recently, in diabetes, cancer, heart disease, and neurodegeneration. The etiology of many of these diseases arises from specific genetic mutations in E1, E2, or E3, while others result from abnormal regulatory control of PDH by the kinases and phosphatases.

Small Metabolite Regulation of PDH

PDH activity is modulated by ratios of ATP/ADP, NADP/NAD⁺, and acetyl-CoA/CoA, and by phosphoenolpyruvate, pyruvate, and ions, that act as indicators of the metabolic state of the cell. Inhibition of the complex occurs when the cell is in an energy-rich metabolic state, reflected by high concentrations of ATP, NADH, and acetyl-CoA. When the concentration of these metabolites declines, and levels of AMP, CoA, and NAD⁺ rise, activation of the complex occurs. Atomic X-ray structures of the E2 catalytic core and the E3 dihydrolipoyl dehydrogenase reveal that acetyl-CoA and NADH are product inhibitors, because they compete for the binding sites of CoA and NAD⁺, respectively. Other metabolites influence the phosphorylation state of the PDH as discussed below.

PDK Regulation of PDH

There are four PDH kinase isoforms (PDK1–4) that regulate the activity of PDH by modulating the phosphorylation state of E1. These are not related to cytoplasmic Ser/Thr/Tyr kinases, but are distantly related to protein histidine kinases. Upon activation, these kinases undergo autophosphorylation on a conserved histidine residue before transfer of the high-energy phosphate to the acceptor substrate protein. There is considerable variation in the kinetic parameters and regulation of the different PDKs, as well as in their amino acid sequences, although each isoform is highly conserved between mammalian species. PDK1 is present in heart, skeletal muscle, and pancreatic islets. PDK2 is ubiquitously expressed in mammalian tissues and is particularly sensitive to metabolic signals for energy demand and fuel source. It is expressed at higher levels during starvation and diabetes. PDK3 has the highest specific activity of all of the PDKs. It is typically expressed at low levels in most tissues except in testis, kidney, and brain. PDK4, which is expressed at higher levels during starvation and diabetes, is normally expressed at low levels except in heart, skeletal muscle, and pancreatic islets and has the highest basal activity among the PDKs. Insulin represses PDK4 expression, but loss of this regulation leads to elevated blood glucose levels present in insulin-unresponsive patients. Thus, multiple isoforms are expressed in specific tissues simultaneously. Different isoforms can form functional heterodimers that have different kinetic

and regulatory properties than those of the parent homodimers. These add to the complexity of regulation, especially when taken together with differential expression of the PDH phosphatases PDP1 and PDP2. Hormonal regulation and a number of disease states, other than diabetes, can also alter PDK expression significantly. For example, PDK3 and PDK1 are overexpressed in hypoxic cancer cells by the actions of the transcription factor hypoxia-inducible factor-1 (HIF-1). This shifts cellular metabolism to generate high levels of lactate through the activation of glycolysis and the reduction of mitochondrial oxidative pathways (Warburg effect). The PDPs often show opposite patterns of expression to those of the PDKs, thus further amplifying the regulatory effects on PDH activity. Both the PDKs and PDPs are attractive targets for drug design. A number of compounds, including the nonhydrolyzable pyruvate analog dichloroacetate (DCA), have been considered as potential therapeutic agents for diabetes, lactic acidosis, myocardial ischemia, and cancer.

E1 activity can be inhibited by phosphorylation of any of three target Ser residues on its α -subunit. The PDK isoforms show significant variation in their specificity toward individual phosphorylation sites: each can phosphorylate Ser 264 (site 1) and Ser271 (site 2), albeit with different rates, but only PDK1 modifies Ser203 (site 3). These phosphorylation sites are located on two adjacent loops that are close to the active site of E1. Structural studies of human E1 indicate that phosphorylation of site 1, which blocks the majority of E1 activity, disorders two loops adjacent to the E1 active site and disrupts the interaction of ThDP and the E2-bound lipoyl group with their respective binding sites on E1 (**Figure 2(a)**). Phosphorylation of sites 2 and 3 occurs more slowly and is thought to hinder reactivation of E1, primarily by PDP2.

The influence of small molecule and ion regulators on the kinases is complex, although many work by modulating interactions of the enzyme with the inner lipoyl domains of E2. NADH and acetyl-CoA cause the reduction and acetylation of the E2-associated lipoyl groups through reversal of the reactions normally catalyzed by E3 and E2. The modified lipoyl domains (L2) can bind each PDH kinase isoform with a gradation of affinities PDK3 > PDK1 ~ PDK2 > PDK4. Binding to L2 situates each kinase in close proximity to the E1 substrate, and modestly increases activity of PDK2 and PDK3. PDK3 alone is activated strongly by L2 domains associated with the native E2 core or free in solution, indicating that it is also allosterically activated by L2. PDK1 and PDK4, with high intrinsic basal activities, show marginal effect of L2 association. However, for all isoforms, this interaction may be crucial for the movement of limited numbers of kinases around the E2 core. Studies on PDK2 indicate that in the presence of potassium phosphate buffer, ADP and pyruvate (or DCA) slow ADP dissociation and strengthen product inhibition while markedly reducing L2 binding and shifting the dimer to an inactive tetrameric state. Similar effects are seen in PDK1 and PDK4, but not in PDK3, which is not regulated by pyruvate.

X-ray crystallographic analysis of multiple PDK isoforms in the absence or presence of key regulatory compounds provides a satisfying glimpse into the alterations in active site geometry that underlie the action of many of these regulators. Each monomer has two domains of similar size. The N-terminal regulatory domain is a four-helix bundle that binds the lipoyl

Figure 2 Inactive and active conformations of E1 and PDK. (a) Binding of ThDP (magenta) to the active site of E1 induces ordering of the phosphorylation loops A (orange line) and B (yellow line) which enables the decarboxylation of pyruvate (tan) and the reductive acetylation of the lipoyl group attached to the lipoyl-binding domain, Lip-LBD. Numbered circles represent the three phosphorylation sites; hydrogen bonds are shown by dotted black lines; a water molecule is indicated by a red dot; the E1 α - and β -subunit are green and cyan, respectively. (b) Phosphorylation of site 1 (Ser 264) in human apo-E1 blocks ordering of the phosphorylation loops, reduces the binding of ThDP, abolishes the hydrogen-bonding network that is required to order the loops and blocks access of the lipoyl substrate, resulting in inactivation of E1 catalysis. Disordered phosphorylation loops are indicated by yellow and orange dashed lines. (c) Closed (left), intermediate open (middle), and open (right) conformations of PDK isoforms. In the presence of high-affinity ADP binding (red circled N), PDK2 has a closed active site cleft, with fully disordered C-terminal tails. Apo-PDK2 or PDK4-ADP structures are in an active, intermediate open conformation which has an open active site cleft with low-affinity nucleotide-binding sites (pink circled N) and C-terminal tails that interact with the other subunit using the DW motif anchor sites (red circles), although the terminal amino acids of the tail remain disordered. The active open conformation evident in the PDK3-L2-ADP and PDK2-L2-AMPPNP structures has an open active site and fully ordered C-terminal tails which cross-anchor the subunits and help form the L2-binding domain. Molecules that induce transitions between the three states are indicated above and below the arrows. AZD7545 is a dihydrolipoamide mimetic. The PDK subunits are shown in blue and green, with the N- and C-terminal domains indicated. Solid and dashed lines indicate ordered and disordered regions of the protein, respectively. L2 is shown in yellow. (a, b) Reproduced from Kato M, Wynn RM, Chuang JL, et al. (2008) Structural basis for inactivation of the human pyruvate dehydrogenase complex by phosphorylation: Role of disordered phosphorylation loops. *Structure* 16: 1849–1859, with permission. (c) From Wynn R, Kato M, Chuang JL, Tso S-C, and Chuang DT (2008) Pyruvate dehydrogenase kinase-4 structures reveal a metastable open conformation fostering robust core-free basal activity. *Journal of Biological Chemistry* 283: 25305–25315.

group of L2, pyruvate, and other regulatory ligands. The C-terminal catalytic domain contains α -helical and β -sheet motifs, an ADP/ATP nucleotide-binding site where phosphoryl transfer occurs, a large dimerization interface that results from head-to-tail interactions of the β -sheets of the two subunits, and a C-terminal tail that modulates the switch from inactive to active states of the kinase. The active site of each monomer localizes to the interface between the regulatory and catalytic domains, where ATP/ADP binds to an ATP-binding fold unique to the GHKL superfamily of ATPase/kinases. This fold has an

associated structural loop element called an ATP lid, whose conformation is regulated by ATP hydrolysis, as well as by regulatory signals initiated and transmitted from distal regions of the kinase.

Multiple conformations of the enzyme have been identified (Figure 2(b)). In the inactive closed conformation, the C-terminal tail is disordered and does not interact with the other subunit. The ATP lid interacts with the N-terminal domain, preventing ADP dissociation to maintain product inhibition. L2 binding is required to obtain the active state in which the N-proximal region of the C-terminal tail containing

a conserved Asp-Trp (DW) motif of one subunit wrap around the other subunit and also interact with specific amino acids of the L2 domain. The C-terminal amino acid residues of one subunit are an integral component of the lipoyl-binding domain of the other subunit. These interactions widen both the active site cleft and the dimer interface by destabilizing the interaction of the ATP lid with the N-terminal domain. In turn, this facilitates exchange of ATP for bound ADP and likely also increases the accessibility of target serine residues of E1 to the γ -phosphate of ATP, which is transferred to the substrate serine once it has been activated by a conserved amino acid that acts as a general base during the phosphoryl transfer reaction. Other structural rearrangements have also been observed. For example, in PDK2, there is ordering of a loop that forms the back wall of the E1 binding site, which encompasses both the lipoamide binding pocket and adjacent amino acids that specifically interact with the L2 domain itself. An intermediate active state of PDK4 has been crystallized in the presence of ADP that has an open active site cleft and partially ordered C-terminal tails. The effective removal of ADP by PDK4 in this state requires the DW motif; its loss ablates the robust core-independent basal activity of PDK4.

An important mechanism by which signals are transmitted between the nucleotide-binding site and the L2-binding domain may be provided by a long central rod located near the two sites. This rod is composed of two short helices that link the two sites. A central pyruvate/DCA-binding site sits between the two helices (Figure 3). The geometry of the active site is influenced by its nucleotide occupancy, pyruvate, and L2 binding, and, surprisingly, by K^+ ions. Analysis of human PDK2 with bound DCA indicates that the β -phosphate of ADP chelates K^+ , together with backbone carbonyl groups of three amino acids, and an oxygen atom of a Ser hydroxyl group, to enhance ADP inhibition. Binding of lipoyl domain shifts the arrangement of the participating amino acid residues, disrupts the K^+ binding site, and enhances dissociation of ADP from the active site. Binding of K^+ ions at other sites on the protein stabilizes the L2-binding site and facilitates cross-talk

Figure 3 Binding of the pyruvate analog DCA induces conformational changes in PDK1. Apo-PDK1 (pink ribbon) undergoes small movements of helices 6 (orange) and 7 (yellow), and unwinding of a short linker region upon binding of DCA (green space-filling model). DCA-bound PDK1 is shown as a green ribbon. Movement of this helical rod may mediate cross-talk between the nucleotide-binding site and its associated ATP lid (red), the lipoyl-binding site (magenta), and the pyruvate/DCA-binding site. Reproduced from Kato M, Li J, Chuang JL, and Chuang DT (2007) Distinct structural mechanisms for inhibition of pyruvate dehydrogenase kinase isoforms by AZD7545, dichloroacetate, and radicicol. *Structure* 15: 992–1004, with permission.

between the nucleotide- and L2-binding sites. Although much less is known about their regulation, ions are also important regulators of PDP1 and PDP2. Both forms are activated by increasing concentrations of free intra-mitochondrial Mg^{2+} or Mn^{2+} that occur in response to declining levels of ATP. Increases in free mitochondrial Ca^{2+} activate PDP1 in tissues with hormonal or exercise-dependent increases in mitochondrial Ca^{2+} . The ion serves to bridge the interaction of PDP1 with L2 domain of E2, thereby stimulating phosphatase activity. The activities of PDK and PDP2 are regulated in reciprocal fashion by inositol phosphoglycans, compounds that chelate Mn^{2+} and Zn^{2+} metal ions and that are generated in response to stimulation by insulin.

Architecture of PDHs by Cryo-Electron Microscopy

While visualization and extensive biochemical analysis of the individual PDH components have yielded detailed information about the mechanism and regulation of the complex, additional possibilities for how the three enzymes integrate to form a highly efficient multifunctional catalytic machine have been provided by cryo-electron microscopic analysis. Two-dimensional projection images of the complex reveal the general structural arrangement of the central core decorated by peripheral subunits (Figure 4(a)) but the three-dimensional reconstruction of complexes from bacteria, yeast, and mammalian E2 cores in the absence or presence of peripheral E1 or E3 subunits indicates a surprising diversity in detailed structural arrangements of each type of complex.

In PDH subcomplexes of *B. stearothermophilus*, in which the E2 core is fully decorated with E1 or E3, the outer shell of peripheral subunits localizes ~ 75 – 100 Å above the E2 catalytic core (Figures 4(b) and 4(d)). This structural architecture may increase productive substrate channeling because the active sites of E1, E2, and E3 each face the annular gap. The swinging lipoyl domain may also preferentially localize to the gap, increasing its effective concentration, at least when the number of peripheral subunits bound to the complex is high. Three-dimensional snapshots of individual complexes obtained using cryo-electron tomography indicate that the peripheral enzymes localize well above the core, even in lightly decorated complexes although their arrangement deviates from the strict icosahedral symmetry present in the inner core. Similar architectural features are evident in the octahedral complexes present in *Escherichia coli*. In *B. stearothermophilus*, lateral movements of the subunits above the core can extend the effective reach of the swinging arm since a lipoyl domain associated with a specific E2 monomer potentially can contact up to 12 peripheral subunits. Radial movements of the outer enzymes toward the core, possibly through the transient formation of a type VI turn in the inner semiflexible linker, may maintain the peripheral subunits in close proximity to each other and the core to facilitate catalysis. This is particularly relevant for E3 given that few enzymes populate each complex. Yeast PDH also maintains E3 close to the core, albeit by more direct interactions with the pentagonal face of the inner E2 core.

Mammalian PDHs have different constraints than their bacterial counterparts: while E3 is more plentiful and potentially more symmetrically distributed around the E2 core, the

Figure 4 Architecture of icosahedral pyruvate dehydrogenases (PDHs) from cryo-electron microscopic analysis. (a) Cryo-electron microscopic images of a PDH subcomplex from *B. stearothermophilus* consisting of E2 icosahedral core decorated with 60 E1 enzymes are used to reconstruct a three-dimensional model (b). Sectioned schematic view of this model highlights three E2 molecules (colored red, green, and yellow) and shows the movement of the swinging E2 lipoyl domain in the annular region between the inner core (cyan) of E2 molecules and the outer shell of E1 molecules (purple). (c) Sectioned view of a three-dimensional reconstruction of the bovine PDH showing the E2 inner core (green), outer E1 shell (yellow), and rigid inner E2 linkers (blue). (d) Active site coupling between E1, E2, and E3 mediates the synthesis of acetyl-CoA from pyruvate. An acetyl group from pyruvate is covalently attached to the lipoyl domain at the active site of E1 (left-hand side) and is transported across the annular gap to an E2 active site (center) where it is transferred to CoA. The dithiolane ring of the lipoyl domain is then regenerated at an E3 active site (far right-hand side) present in the outer protein shell of the complex. The PDH complexes shown in panels a, b, and c are ~ 450 Å in diameter. (a, b) Reproduced from Milne JLS, Shi D, Rosenthal PB, et al. (2002) Molecular architecture and mechanism of an icosahedral pyruvate dehydrogenase complex: A multifunctional catalytic machine. *EMBO Journal* 21: 5587–5598, with permission. (c) Reproduced from Zhou H, McCarthy DB, O'Connor CM, Reed LJ, and Stoops JK (2001) The remarkable structural and functional organization of the eukaryotic pyruvate dehydrogenase complexes. *Proceedings of the National Academy of Sciences of the United States of America* 98: 14802–14807, with permission.

kinases and phosphatases that bind to the inner lipoyl domain prior to interaction with E1 must have clear accessibility to the interior of the complex. The inner linker that joins the inner E2 domain and the peripheral subunit-binding domain is more ordered in the region adjacent to the core. Upon E1 binding, the linker is thought to become even more rigid, since density for this region can be visualized in bovine PDH complexes (Figure 4(c)). The E2 monomers also integrate into a relatively dynamic central icosahedron that exhibits variation in size. These modifications likely enhance active site coupling in annular gaps that are more crowded than those found in bacteria, and promote interactions between E1 and the regulatory kinases and phosphatases. In addition, while both bacterial and eukaryotic enzymes are thought to transfer acetyl groups between adjacent lipoyl domains, the eukaryotic complexes additionally could require the movement of the

regulatory enzymes accomplished through coordinated interactions with both E1 and the lipoyl domains of E2 in a hand-over-hand transfer mechanism.

Conclusion

The biochemical and structural studies of PDH components over the last six decades have led to extraordinary insights into the functioning of one of the central players in cellular metabolism. Our present knowledge of PDH mechanism thus ranges from atomic resolution details of substrate interactions and channeling at the active sites of E1, E2, and E3 to the higher-order architecture and regulation by kinases and phosphatases. These studies have also produced fascinating glimpses of how PDH function is altered in response to changes in its chemical

environment and how transcriptional control of PDH and PDK genes *in vivo* may be used to modulate function. Integrating the knowledge derived from these analyses to predict the dynamic structural and functional aspects of PDH in the complex milieu of intact cells in healthy and diseased states is undoubtedly an exciting challenge for the future.

Glossary

b_n , Q_n and b_p , Q_p Hemes, quinones bound on electrochemically negative or positive sides of membrane, the chloroplast stroma and lumen, respectively.

Cyclic electron transport Electron transport around photosystem I via plastoquinone and the cyt b_6f -complex which provides extra ATP.

Photosystem The total of pigments assembled around a reaction center.

Q-cycle A mechanism of proton translocating quinol oxidation by cyt bc-complexes in respiratory and photosynthetic electron transport, first formulated by Peter Mitchell in 1975.

Thylakoid Coined by Wilhelm Menke to denominate the structure of the inner membrane system of the chloroplast which in cross-section appears to be built from stacked little bags, but their inner space is connected in the third dimension.

Function

The oxygenic photosynthetic electron transport chain embedded in a lipid membrane transduces the light energy absorbed and transferred from light-harvesting pigments and reaction center complexes (~ 1.8 electron volts ≈ 40 kcal mol $^{-1}$ per red light photon) to free energy stored in the high-energy bond of adenosine triphosphate (ATP) and reducing equivalents stored in pyridine nucleotide (nicotinamide adenine dinucleotide phosphate (reduced), NADPH). The 220-kDa hetero-oligomeric cytochrome b_6f complex dimer is one of three multisubunit integral membrane protein complexes in the photosynthetic electron transport chain, transferring electrons from the H $_2$ O electron donor to the nicotinamide adenine dinucleotide phosphate (NADP) $^{+}$ acceptor. Through the coupling in the b_6f complex of electron transport to proton translocation, a trans-membrane proton electrochemical potential gradient ($\Delta\tilde{\mu}_{H^{+}}$) is generated as the intermediate high-energy intermediate to provide the free energy, ΔG_{ATP} , required for ATP production, discharging the proton gradient through the ATP synthase (Figure 1). With as many as four protons/ATP the ΔG_{ATP} is equal to the number of protons, n , transferred through the ATP synthase per ATP synthesized, that is, $\Delta G_{ATP} \approx n\Delta\tilde{\mu}_{H^{+}}$.

The other two hetero-oligomeric protein complexes in the oxygenic photosynthetic electron transport chain in chloroplast thylakoid or photosynthetic microbial membranes are the dimeric photosystem II (PSII) and trimeric photosystem I (PSI) reaction center complexes. The b_6f complex functions between the two reaction center complexes in the linear electron transport chain from H $_2$ O to NADP $^{+}$ (Figure 1). The complex accepts electrons and protons from the PSII complex via a pool in the membrane bilayer of lipophilic plastoquinone/ol, PQ/PQH $_2$, whose chemical structure consists of a substituted benzene ring connected to a carbon chain of nine isoprenoid groups, that is, 45 carbons. The electron affinity of PQ/PQH $_2$ ($E_{m7} = +100$ mV) is intermediate between that of the bound quinone, Q_A , in the PSII reaction center

and the two iron–two sulfur [2Fe–2S] cluster ($E_{m7} = +300$ mV) of the Rieske iron–sulfur subunit (ISP) in the b_6f complex. Transfer of one electron from PQH $_2$ to the [2Fe–2S] cluster, which generates the neutral semiquinone radical, PQH $^{\bullet}$, is coupled to transfer of a proton to a histidine ligand of the cluster, and then to the p-side aqueous phase, thereby contributing to the $\Delta\tilde{\mu}_{H^{+}}$. The [2Fe–2S] cluster donates an electron to the heme of cytochrome f (f , feuille, leaf) and to the PSI complex through the soluble copper-containing plastocyanin or cytochrome c_6 (Figure 1). The detailed pathways of electron and proton transfer responsible for electrogenic proton translocation and generation of the $\Delta\tilde{\mu}_{H^{+}}$ are centered on a Q cycle, discussed below, and shown in Figure 4.

Crystal Structures

The photosynthetic electron transport/proton translocation complexes shown in Figure 1 are integral membrane–protein complexes that can only be isolated and purified after extraction in detergent from the host membrane. The detergent(s) that allow purification of a given membrane–protein complex in an active and crystallizable state must be determined for each protein complex. Maltoside detergents have been used to purify the complex. In the initial stages of the crystallization studies of the complex, mass spectroscopy (electrospray) was essential in the development of the purification. The moderately thermophilic cyanobacteria, *Mastigocladus laminosus* and *Nostoc* sp. PCC 7120, and the green alga, *Chlamydomonas reinhardtii*, have been the sources for crystallization and crystallography studies of the b_6f complex. The purification of the complex from *C. reinhardtii* utilized affinity tagging/chromatography. A major gap in the structure studies of the b_6f complex is the absence of a structure from a plant source.

Each monomer of the b_6f complex contains 13 membrane-spanning α -helices in which seven prosthetic groups are embedded. The two monomers are arranged with a C2

Figure 1 The electron transport/proton translocation chain of oxygenic photosynthesis showing structures of the membrane-embedded multisubunit energy-transducing complexes, except for the NDH-1 complex, not yet solved. Left to right, NDH-1, hetero-dimeric photosystem II reaction center, homo-dimeric cytochrome *b₆f* complex, trimeric photosystem I reaction center complex, and ATP synthase. Maximum $H^+/2e^-$ ratio = 2 for PSII and 4 for the *b₆f* complex; proton stoichiometry of protons utilized for ATP synthesis to ATP synthesized, H^+/ATP , = 4.

symmetry that is relevant for function. A schematic of the complex is shown in a stick model that shows the position of the seven prosthetic groups, which is a dimer with C2 symmetry (Figure 2). The monomer contains eight trans-membrane α -helical subunits, four ‘large’ subunits (cytochromes *f* and *b₆*, the Rieske iron–sulfur [2Fe–2S] protein (ISP), and subunit IV, with molecular weights between 18 and 32 kDa), and four small hydrophobic subunits (petG, L, M, and N), 3–4 kDa, each punctuated by 1–2 positive residues on the n-side, which can be characterized as hydrophobic sticks and span the membrane with one trans-membrane α -helix. These four small subunits form a picket fence-like structure on the periphery of each monomer. The molecular weights of the subunits of the *M. lamosus* complex, and the midpoint oxidation–reduction potentials of the redox prosthetic groups determined *in situ* (in membranes), are summarized (Table 1).

Prior to determination of the structure of the *b₆f* complex, the soluble domains of cytochrome *f* and the Rieske [2Fe–2S] protein were solved. It is of interest that both p-side (lumen) redox proteins are predominantly β -strand, as is the p-side plastocyanin. This secondary structure for cytochrome *f* is virtually unique for a c-type cytochrome. In this respect, and also in its primary amino acid sequence, cytochrome *f* and cytochrome *c₁* of the *bc₁* complex are completely different proteins. The only common feature is the characteristic five-residue Cys–X–Y–Cys–His heme-binding sequence that is diagnostic of c-type cytochromes. The 217 070 and 214 298 molecular weight (without prosthetic groups) *b₆f* complex from *M. lamosus* and *Nostoc*, respectively, is a symmetric dimer.

A salient feature of the structure, in which the 24-kDa cytochrome *b* and 18-kDa subunit IV forms the core, is the set of seven tightly bound prosthetic groups, of which five are bound redox groups (four hemes, cyt *f*, two noncovalently bound *b*-hemes and one covalently bound *c* heme, the unique heme *c_n* (Figure 3)) bound to the cyt *b* polypeptide. Together

with the [2Fe–2S] cluster, these groups define a Q-cycle pathway for quinol oxidation (Figure 4), in which the transfer of the two electrons derived from the oxidation of PQH₂ is split into low- and high-potential chains, respectively, transferring an electron (1) through the low-potential branch consisting of the two *b*-hemes ($E_{m7} \approx -0.05$ to -0.10 V) across the complex to a quinone, PQ_n, bound on the n-side of the complex; (2) through a high-potential chain consisting of the [2Fe–2S] cluster ($E_{m7} \approx +0.3$ V), the high covalently bound heme of cytochrome *f* ($E_{m7} \approx +0.35$ V), to the PSI reaction center via a soluble heme or copper protein (Figure 4). With no electrochemical restraining forces, the result of the oxidation of two PQH₂ molecules would be the transfer of 2 H⁺ to the p-side aqueous phase for each electron transferred to the high potential chain, that is, $H^+/e = 2$.

Important consequences of the C2 symmetry of the dimer

Although a C2 symmetry is not surprising for a dimeric protein, it has important consequences for the binding and passage of the quinone molecules with their extended isoprenoid tail: (1) Quinones bound on either the p- or n-side will have much less steric interference as a result of their position on the opposite side of the complex. (2) The trajectory of the quinone across the complex, from n- to p-side, or p- to n-, will occur on one lateral surface of the complex, thus avoiding possible hindrance imposed by fatty acyl chains in the inter-monomer cavity.

The Quinone-Exchange Cavity

The space between the two monomers is ~ 30 Å high $\times$ 15 deep and 25 Å wide (Figure 1). The walls of the two cavities on opposite sides of the dimer are formed by transmembrane helices (TMHs) from each monomer: the ‘C, D’ TMH of the cytochrome *b* subunit, the ‘F’ TMH from the subunit IV subunit from one monomer, and the ‘A, E,’ and ISP TMH from

Figure 2 Stick diagram of the symmetric dimeric cytochrome *b₆f* complex, with 13 membrane-spanning α -helices per monomer, derived from the 3.0 Å crystal structure of the cyanobacterium *Nostoc* sp. PCC 7120 (pdb, 2ZT9). Color code: p-side of complex: cyt *f* (*petA*), brown; Rieske ISP (*petA*), yellow; cyt *b* (*petB*), blue; subunit IV (*petD*), brown; petG, L, M, N, gray, green, brown. The bound Chl *a* and β -carotene are shown in dark green and blue. The core of the complex consists of (i) the 24-kDa cytochrome *b* with four trans-membrane helices, the 18-kDa subunit IV (3 TMH), and the single TMH of the Rieske [2Fe–2S] subunit that spans the complex from the soluble domain containing the [2Fe–2S] cluster on the p-side of one monomer across the complex to the n-side of the other. The complex contains seven tightly bound prosthetic groups, of which five are bound redox groups: four hemes (cytochrome *b* in the p-side soluble domain), two noncovalently bound *b*-hemes, *b_p* and *b_n*, that span the complex and one covalently bound *c* heme, the unique heme *c_n*. There are two additional nonredox prosthetic groups, one chlorophyll *a* and one β -carotene whose function is not clear, but which define one of the differences between the *b₆f* and cytochrome *bc₁* complexes. β -Carotene quenches the excited triplet state of the chlorophyll even though the two pigment molecules are separated by 14 Å and can thereby protect the protein network against damage from singlet oxygen. The distances between the prosthetic groups in the *M. lamosus* and *Nostoc* structures are summarized (Table 2).

Quinone-exchange cavity. The cavity between the two monomers is ~30 Å high, 15 Å deep, and 25 Å wide. The boundaries of each of the cavities, which are on opposite sides of the dimer, are formed by trans-membrane helices from each monomer: the C, D TMH of the cytochrome *b* subunit, which contains TMH A–D. The cavity walls are also lined by the F TMH from subunit IV, from one monomer, and the A, E, and ISP TMH from the other. The cavity is probably filled with disordered lipid acyl chains. The structure obtained with a co-crystallized n-side quinone analog inhibitor (pdb: 2E75, 2E76) suggests that the unique heme *c_n* (Figure 3), together with heme *b_n* to which it is electronically coupled, serves as the n-side quinone reductase. The p-side soluble domains of cytochrome *f* and the ISP are predominantly β -strand, as is the p-side plastocyanin. The β -structure for cytochrome *f* is virtually unique for a *c*-type cytochrome. In this respect, and also in its primary amino acid sequence, cytochrome *f* and cytochrome *c₁* of the cytochrome *bc₁* complex are completely different proteins, the only common feature being the characteristic 5-residue Cys–X–Y–Cys–His heme-binding sequence diagnostic of *c*-type cytochromes. Seven lipid-binding sites are found in the structures (not shown), one natural site occupied by an n-side sulfolipid, two sites occupied by DOPC lipid that was used for crystallization and presumably displaced natural lipid, and four sites occupied by UDM detergent molecules.

the other. The true dimensions of the cavity are probably smaller than stated above because the cavity is filled to a large extent with lipid acyl chains. This has not been documented in the crystal structures of the *b₆f* complex, which show seven lipid-binding sites per monomer, but is inferred from the 11 lipids including some acyl chain structures that are resolved in the structure of the yeast *bc₁* complex.

The Unique Heme *c_n*

The presence of heme *c_n* was first detected in intact cells (*in vivo*) by sensitive difference visible light spectrophotometry. Subsequently, in studies with purified *b₆f* complex, heme *c_n* was shown by perpendicular and parallel mode electron paramagnetic resonance (EPR) to be electronically coupled to heme *b_n*, the heme on the n-side of the complex, to be present in *b₆f* complex from spinach thylakoids from which a crystal

structure has not yet been determined, the cyanobacterial *b₆f* complex, and the green alga, *C. reinhardtii*. The crystal structure shows that the distance between *c_n* heme Fe and propionate of heme *b_n* is ~4.0° Å, bridged by an OH[−] ion or H₂O. The proximity between hemes *b_n* and *c_n* is reflected in the strong electronic coupling between the two hemes, as shown by orthogonal and parallel mode EPR spectra of the isolated complex with *g* values as large as 12. Heme *c_n* does not contain any amino acid side chain as an axial ligand (Figure 3). This structural feature makes it a unique heme in all of biochemistry.

Structure: Rotational Isomers of Heme *b_p*

Somewhat remarkably, as seen by the positions of the methyl and vinyl side chains of the heme, the heme plane of heme *b_p* in the *M. lamosus* *b₆f* complex is rotated by 180° about the normal to the membrane plane relative to this heme in

Table 1 Molecular weights and midpoint oxidation–reduction potentials (E_{m7}), values associated with the subunits of the *M. lamosus* cyanobacterial cytochrome *b₆f* complex

Subunit	M_W (Da)	Midpoint redox potential of prosthetic group E_{m7} (mV)
Cyt <i>f</i> (heme) [PetA]	32 273	+350–380
Cyt <i>b₆</i> (two hemes) [PetB]	24 712	(–50 (<i>b_n</i>); –50 to –100 (<i>b_p</i>)) ^a , +100 (heme <i>c_n</i>) ^b
ISP (2Fe–2S)[PetC]	19 295	+295 (pH 6.5) to +320
sulV [Pet D]	17 528	–
PetG	4 058	–
PetM	3 841	–
PetL	3 530	–
PetN	3 304	–

The uncertainty in the E_{m7} values is $\approx \pm 20$ mV.

**Figure 3** Structure and environment of heme *c_n*; arrangement of hemes *b_p*, *b_n*, and *c_n*. The two bis-histidine coordinated *b*-hemes are separated by 7–8 Å edge–edge (pdb: 2E74, 2ZT9) along the direction normal to the membrane plane. Heme *c_n* is positioned on the edge of the intermonomer quinone exchange cavity, with an OH[–] bridging across 4 Å the heme *b_n* and the Fe atom of heme *c_n* (Table 2). The heme is covalently linked via a single thioether group to Cys35 on the n-side of the A TMH of the cyt *b* subunit and, as shown by EPR spectra, electronically coupled to heme *b_n*.

the complex in the *Nostoc* cyanobacterium or in the *C. reinhardtii* alga. The consequences of these rotameric states are not understood.

Structure: Posttranslational Modification of the Iron–Sulfur Protein

Mass spectroscopic analysis has shown that the Rieske protein in the *Nostoc* complex is acetylated at the N-terminus, a

posttranslational modification that is unprecedented in cyanobacterial membranes, and in cytochrome *bc* complexes from any source.

The Chlorophyll and β -Carotene Nonredox Prosthetic Groups

There are two additional prosthetic groups bound to the complex, a chlorophyll *a* and a β -carotene. The β -carotene is able to quench the excited triplet state of the chlorophyll even though the two pigment molecules are separated by 14 Å. The β -carotene can thereby protect the protein network against damage from singlet oxygen. Given this elaborate protection system, the function of the chlorophyll, although unknown, must be important. The prosthetic groups are organized around the central quinone-exchange cavity (Figure 2).

Amino Acid Sequences of Subunits

Amino acid sequences of subunits are as follows: (1) *Mastigocladus laminosus b₆f* complex: (i) gene sequences (*petA*, *B*, *C*, *D* genes), (NCBI accession numbers AY390356 and AY390357); (ii) amino acid sequences in PDB accession code 2E74; (2) *Nostoc* sp. PCC 7120 *b₆f* complex: (i) sequence of entire genome including cyt *b₆*, 215 amino acids (aa); apocytochrome *f*, 333 aa; Rieske iron–sulfur protein, 178 aa; subunit IV, 160 aa; *petG*, 37 aa; *petL*, 31 aa; *petM*, 34 aa; *petN*, 29 aa, in PDB, 2ZT9; (ii) *Chlamydomonas reinhardtii b₆f* complex (PDB, 1Q90).

Function

The second p-side turnover of PQH₂ can transfer a second electron to PQ_n or the plasto-semiquinone, PQ[•], on the n-side of the complex, regenerating PQH₂. Thus, the *b₆f* complex functions as a plastoquinol: plastocyanin/cytochrome *c* oxidoreductase on the electrochemically positive (p) side of the membrane and as a plastoquinone reductase on the electrochemically negative (n) side (Figure 4). These transfer events are analogous to those in the *bc₁* complex of the respiratory chain and photosynthetic bacteria. As noted above, the PQ/PQH₂ cycle in the *b₆f* complex differs in several respects from the Q-cycle model initially proposed for regeneration of ubiquinol through function of the cytochrome *bc₁* complex in the respiratory chain and photosynthetic bacteria: (1) the presence of heme *c_n*, which is inferred from crystal structure data to be the PQ reductase, and, from EPR spectra in the presence of NO₂, the PQ oxidase; (2) the electronic coupling between hemes *b_n* and *c_n*, which implies that quinol reduction need not necessarily proceed through a semiquinone intermediate, but perhaps cooperatively through hemes *b_n* and *c_n*, providing protection against the formation of superoxide ion and reactive O₂ species; and (3) the presence of ferredoxin: NADP⁺ reductase (FNR) bound to purified plant (spinach) *b₆f* complex implies that electrons needed for the reduction of PQ to PQH₂ can also be supplied by cyclic electron transport, which can transfer electrons back to the *b₆f* complex and the central electron transport chain via ferredoxin from the reducing side of PSI. Coupling of electron and proton transfer generates a maximum H⁺/e[–] ratio = 2 for proton translocation across the complex from the n- to the p-side aqueous phase.

Figure 4 A Q cycle model for a bifurcated pathway of electron transfer into a high (ISP → cyt *f* → PC → PSI) and low-potential (PQH₂ → heme *b_p* → heme *b_n* → PQ_n) chain, resulting in the transfer of as many as 2H⁺ per electron transferred to the p-side aqueous phase. The NDH (ndh-1) complex, which has not yet been completely purified, is shown as another pathway for reduction of the intra-membrane PQ/PH₂ pool.

Rate-limiting step, activity, and inhibitors

Under conditions of sufficient substrates for carbon fixation, the proton-coupled oxidation of plastoquinol by the Rieske [2Fe–2S] ISP is the rate-limiting step, 1–10 ms, of the electron transport reactions of oxygenic photosynthesis. This step is readily assayed through the kinetics of reduction of cytochrome *f*, the electron acceptor of the ISP. High *in vitro* activity of the isolated *b₆f* complex, ~200 electrons cyt *f*^{–1}, s^{–1}, utilizing the plastoquinone analog, decyl-plastoquinone, reduced by borohydride as the electron/proton donor, and plastocyanin oxidized by ferricyanide as electron acceptor, is an important prerequisite for successful crystallization of the isolated *b₆f* complex. A poor electron-transfer rate implies a damaged or deficient complex. The concentration of *b₆f* complex is assayed routinely through the concentration of cytochrome *f*, determined by the amplitude of the hydroquinone-reduced minus ferricyanide-oxidized difference absorbance spectrum, using a molar extinction coefficient of $2.6 \times 10^4 \text{ M}^{-1} \text{ cm}^{-1}$.

Certain quinol analogs can act as inhibitors of electron transfer in the complex: (1) *p*-side – 2,5-dimethyl, 6-isopropyl benzoquinone (DBMIB), stigmatellin or a tridecyl derivative on the p-side of the complex at the site of quinol oxidation by the ISP; (2) *n*-side – 2-n-nonyl-4-hydroxyquinoline-N-oxide (NQNO) at the site of heme *c_n* that faces the quinone-exchange cavity. NQNO is a much better n-side inhibitor of the *b₆f* complex than is antimycin.

Function: intra-monomer versus inter-monomer electron transfer. The existence of the dimeric structure of cytochrome *bc* complexes can be rationalized on the basis of structure–function considerations involving shielding of hydrophobic surfaces that define the trans-membrane corridor for passage of the lipophilic quinone/quinol. The existence of the dimer raises the question of how it is used for trans-membrane electron transfer, that is, intra-monomer versus inter-monomer pathway. On the basis of the shorter intra-monomer heme distances (Table 2), the intra-monomer heme *b_p*–*b_n* pathway would be favored over a pathway involving p-side cross-over between the two hemes *b_p*.

Table 2 Distances between prosthetic groups of the *b₆f* complex from *M. lamosus* and *Nostoc* sp. PCC 7120

Prosthetic group	Distance (Å)	
	Fe–Fe	Edge–Edge
[2Fe–2S]–Cyt <i>f</i>	29	25, 26
[2Fe–2S]–heme <i>b_p</i>	28	24
Heme <i>b_p</i> –heme <i>b_n</i>	20.6, 20.7	7.4, 8.2
Heme <i>b_p</i> –heme <i>b_p</i>	22.0, 22.1	12.9, 12.7
Heme <i>b_n</i> –heme <i>b_n</i>	35	29
Heme <i>b_n</i> –heme <i>c_n</i>	9.6, 9.7	4 (<i>c_n</i> Fe – <i>b_n</i> propionate)

Distances are very similar in the complex from *C. reinhardtii*.

Evolution

Problems of interest in the evolution of cytochrome *bc* complexes are: (1) the common cytochrome *b* section of the core of *b₆f* and *bc₁* complexes. The conservation of the 4 helix bundle and the trans-membrane portion of the two heme-binding histidine residues in helices 2 and 4, of the heme-binding sites and the distribution of hydrophobicity in the cytochrome *b₆* subunit, and the N-terminal heme-binding half of the cyt *b* polypeptide of the *bc₁* complex implies a common evolutionary origin of the hydrophobic core of *bc* complexes. As evolution led to the addition of different subunits, the *bc₁* and *b₆f* structures diverged in directions parallel and perpendicular to the plane of the membrane. The similarity of evolved function, as an acceptor of electrons from the [2Fe–2S] cluster of the iron–sulfur protein, and almost complete dissimilarity of amino acid sequence and structure of cytochromes *f* and *c₁*, implies convergent evolution of the cyt *f/c* subunits. (2) The comparative evolution of *b₆f* and *bc₁* complexes and the appearance of the heme *c_n*, unique to the *b₆f* complexes, appear to coincide with the emergence of plastoquinone-containing *bc* complexes. (3) The high degree of similarity between the structures of the *b₆f* complex in cyanobacteria and the green alga, *C. reinhardtii*. The crystal structure of the *b₆f* complex at

3.0 Å resolution is essentially identical in the two cyanobacteria that have been analyzed and in the green alga, *C. reinhardtii*, whose appearance on the Earth was approximately 10⁹ years later than that of the cyanobacteria. In both structures, there are eight polypeptide subunits, four (*petA*, B, C, and D) large (M_w = 18–31 kDa) and four (*petG*, L, M, and N) small (M_w = 3.3–4.1 kDa) subunits (Table 1). The root mean square deviation (RMSD) between the 3.0-Å crystal structures from the cyanobacteria *M. laminosus* and *Nostoc* structures, relative to that from the *C. reinhardtii*, are: (1) for the Rieske [2Fe–2S] protein, *M. laminosus* native versus *C. reinhardtii* with the inhibitor, TDS, 1.25 Å; (2) *M. laminosus* TDS structure versus *C. reinhardtii* TDS, 1.06 Å; (3) without the Rieske iron–sulfur protein, *M. laminosus* native structure versus *C. reinhardtii* TDS, 0.98 Å, and *M. laminosus*-TDS structure versus *C. reinhardtii*-TDS, 0.99 Å.

Glossary

A-domain Actuator domain that is involved in the dephosphorylation of the pump.

Cardiotonic steroids Inhibitors of the Na^+, K^+ -adenosine triphosphatase (ATPase) used in the treatment of congestive heart failure.

M-domain Membrane domain containing binding sites for substrate ions.

N-domain Nucleotide-binding domain with a conserved nucleotide-binding residue.

P-domain Highly conserved phosphorylation domain containing the phosphorylation site.

Post-Alberts scheme A reaction scheme describing the transport process as cyclical changes between two states

with different affinities for adenosine triphosphate (ATP) and substrates.

Proton pump inhibitors Inhibitors of the gastric H^+, K^+ -ATPase commonly used in the treatment of gastric diseases such as ulcers.

P-type ATPases Family of membrane-bound ion pumps utilizing ATP and characterized by phosphorylation of a conserved amino acid residue during their functional cycle.

Thapsigargin An effective inhibitor of the sarcoplasmic reticulum Ca^{2+} -pump whose derivatives are currently tested for the treatment of prostate cancer.

P-Type Adenosine Triphosphatase Family

P-type adenosine triphosphatase (ATPases) constitute a large family of evolutionary related membrane proteins that can be found in virtually all living organisms, and are essential housekeeping enzymes in eukaryotes. Members of the family include ion pumps that mediate the thermodynamic uphill movement of cations against their concentration gradients across biological membranes by the use of energy derived from adenosine triphosphate (ATP) hydrolysis. The electrochemical gradients created and maintained by P-type ATPases are essential for survival as they are involved in a number of vital processes mediated by channels and secondary transporters. These include, for example, regulation and maintenance of action potentials in nervous tissues, secretion and absorption of solutes, and control of cell volume, ionic homeostasis and pH (Na^+, K^+ -ATPase), acidification of the gastric juice (H^+, K^+ -ATPase) or relaxation of muscles, and Ca^{2+} -dependent signal transduction (Ca^{2+} -ATPase). Many members of the P-type ATPase family have been implicated in the onset of various diseases such as neurodegenerative disorders arising from the mutations in brain Na^+, K^+ -ATPase or Menkes and Wilson diseases resulting from mutations in copper-transporting ATPases. Consequently, P-type ATPases are clinically important targets; compounds inhibiting the cardiac Na^+, K^+ -ATPase are used in the treatment of congestive heart failure, and inhibitors of the gastric H^+, K^+ -ATPase are the main agents used in the treatment of dyspeptic conditions such as gastric ulcers. Furthermore, P-type ATPases encompass promising targets for a broad range of novel drugs – the sarcoplasmic reticulum Ca^{2+} -ATPase is being developed as a target in the treatment of prostatic cancer, and P-type H^+ -ATPases are attractive targets for novel antifungal agents.

According to analysis of sequence and substrate specificities, P-type ATPases are divided into five subfamilies. While most of the pumps transport cations with a substrate specificity

ranging from monovalent cations such as H^+ , Na^+ , and K^+ (P-type ATPase subfamily II and III) to heavy metals such as Cu^{2+} , Ag^{2+} , Zn^{2+} , Cd^{2+} , or Pb^{2+} (subfamily I), members of the IV (and possibly also V) subfamily are involved in flipping of phospholipids and thus play a role in the maintenance of an asymmetric nature of biological membranes. The number of subunits as well as the size of P-type ATPases vary depending on the subfamily, with the molecular mass ranging from 65 to 150 kDa.

The transport process performed by P-type ATPases follows the post-Alberts reaction scheme that is based on cyclical changes between two main conformational regimes (denoted E1 and E2) that differ in their affinities for ATP and substrates. The term 'P-type ATPases' is used to indicate that a key-conserved residue is phosphorylated and forms an acid-stable aspartyl phosphoanhydride intermediate during their functional cycle.

Structural Studies of P-Type ATPases

Since the Nobel laureate Jens C Skou discovered the Na^+, K^+ -ATPase in 1957, a great amount of work has been done to explore the structural and functional characteristics of the P-type ATPases, with the sarcoplasmic reticulum Ca^{2+} -ATPase from rabbit skeletal muscle (SERCA 1a) currently being the most-studied family member. Using X-ray crystallography, atomic structures representing almost all relevant intermediates in its reaction cycle have been determined at a reasonable resolution, allowing us to understand structural aspects of the transport mechanism. In the case of other pumps such as the Na^+, K^+ -ATPase and the plasma membrane H^+ -ATPase, three-dimensional structures of one of the states of the reaction cycle are available, and biochemical analysis and mutational studies are included to investigate the transport mechanism of these pumps. Moreover, because there is a significant degree of similarity in the overall structure and reaction mechanisms of all

P-type ATPases, structures of different conformations of the Ca^{2+} -ATPase are used as a template for computer-assisted homology modeling for the whole P-type ATPase family.

Sarcoplasmic Reticulum Calcium Pump – A Model Member of the P-Type ATPase Family

The sarcoplasmic reticulum Ca^{2+} -ATPase pumps Ca^{2+} ions from the cytosol of skeletal muscle cells into the sarcoplasmic reticulum store. This gives rise to steep Ca^{2+} gradients that enable fast calcium-mediated signaling and the reuptake of cytoplasmic Ca^{2+} in muscle upon the termination of a contraction event. A low cytosolic concentration of Ca^{2+} maintained by the Ca^{2+} -ATPase is also necessary for other cellular processes, including neurotransmission, neurosecretion, and egg fertilization.

The overall structure of the Ca^{2+} -ATPase consists of four well-defined protein domains connected by linkers in a complex topology (Figure 1). These domains, named according to their function or position, are the M-domain (membrane domain) and three cytosolic domains – P for phosphorylation

domain, N for nucleotide-binding domain, and A for actuator domain. The P-domain contains the phosphorylation site of the pump and its sequence is highly conserved throughout the P-type ATPase family. It is composed of two parts – a central N-terminal part with the phosphorylation motif featuring a conserved aspartate residue (Asp 351 in SERCA 1a) and a C-terminal part that surrounds the phosphorylation motif as two hemispherical subdomains denoted P-I and P-II. The P-II subdomain includes an important and well-conserved signature motif present in all P-type ATPases, encompassing another aspartic residue (Asp 703) that along with the phosphorylatable Asp351 coordinates a Mg^{2+} ion during phosphorylation. Two short hinges link to the N-domain inserted in sequence between the N- and C-terminal parts of the P-domain. The N-domain resembles a top-hat and contains a nucleotide-binding site which is highly conserved among all members of the P-type ATPase family. Upon binding of ATP, the adenine base binds to a groove at the lower end of the top hat while the triphosphate part of ATP adopts a bent configuration located outside this groove and cross-linking the N- and P-domain. The smallest of the three cytoplasmic domains – the A-domain – constitutes a central part rich in beta sheets that is capped by a helical

Figure 1 Schematic representation of the structure of the sarcoplasmic reticulum calcium pump (left) and its crystal structure (right) with an inset showing the residues involved in phosphorylation of the pump. A-domain is shown in yellow, P-domain in blue, N-domain in red, transmembrane segments M1-M2 in purple, M3-M4 in green, M5-M6 in wheat and M7-M10 in gray. Amino acid residues forming the TGES motif are highlighted in orange and residues Asp 351 and Asp 701 in cyan. Mg^{2+} and K^{+} ions are depicted as green and red spheres, respectively. The crystal structure is stabilized by aluminium fluoride and thapsigargin shown in gray and orange, respectively. From Olesen C, Sørensen TLM, Nielsen RC, Møller JV, and Nissen P. (2004) Dephosphorylation of the calcium pump coupled to counter occlusion. *Science* 306: 2251–2255.

N-terminal part. The A-domain plays an essential role in dephosphorylation of the pump during its reaction cycle, as it contains several important residues for interactions with other domains including the conserved TGES sequence motif (Thr 181, Gly 182, Glu 183, and Ser 184) that interacts with the phosphorylated Asp 351 residue of the P-domain and catalyzes the hydrolysis of the aspartyl phosphoanhydride. During the reaction cycle, rotation of the A-domain enables the interaction of all three cytosolic domains and actuates the ion transduction coupled to ATP phosphorylation and dephosphorylation. The linkage of the A-domain to the first two transmembrane helices of the M-domain is crucial for the opening and closing of the Ca^{2+} -binding sites. The M-domain consists of 10 transmembrane helices (denoted M1–M10) forming a cylindrical structure in the sarcoplasmic reticulum membrane where it is surrounded by a ring of an irregular bilayer formed primarily by phospholipids. In the E1 state of the pump reaction cycle, two Ca^{2+} ions are coordinated inside the binding cavity between transmembrane helices M4, M5, M6, and M8 with the help of four side-chain carboxyl groups and main-chain carbonyl groups, forming an electroneutral complex that is later exposed to the extracellular/luminal site of the membrane.

Apart from the two binding sites for Ca^{2+} ions, the M-domain possesses several binding cavities for compounds that can inhibit the calcium pump by blocking the opening of its luminal gate for ions. The most powerful inhibitor of the Ca^{2+} -ATPase described so far is thapsigargin, a sesquiterpene lactone derived from a Mediterranean plant *Thapsia garganica*, whose derivatives, able to selectively target cancer cells, show promise in the treatment of slowly growing prostate cancer cells that are resistant to other cancer therapies. Inducing only a few changes in the structure, thapsigargin binds to a cavity between helices M3, M4, M5, and M7, immobilizing them and thus trapping the pump almost irreversibly in the E2 state that prevents calcium binding and thus the E2 to E1 transition (Figure 1). Another group of inhibitors, represented by cyclopiazonic acid and 2,5-di-(*t*-butyl)-dihydroxybenzene, block a cavity formed by helices M1, M2, M3, and M4, presumed to represent the cytoplasmic access channel for calcium leading to an important glutamate residue Glu 309, which acts as a carrier of Ca^{2+} moving up and down with the M4 helix as the pump changes its conformational state.

Structural Changes during the Calcium Pump Reaction Cycle

Conformational changes in the pump structure during the transport cycle are a result of coordinated movements of transmembrane helices connecting the phosphorylation site at the P-domain with the cation-binding sites in the M-domain. These changes, induced by ion and ATP binding, are enabled by the energy derived from the two-step ATP hydrolysis at the phosphorylation site. While significant rearrangement occurs in the M-domain during the transport cycle, each of the P-, N-, and A-domains move almost as rigid bodies. Importantly, all steps in the reaction cycle are reversible.

The Ca^{2+} transport cycle of the calcium pump starts with the binding of two Ca^{2+} ions from the cytoplasm to the E2 state of the ATPase activating the phosphorylation site. In the

ATP-bound E2 state, the A-domain is rotated toward the phosphorylation site and interacts closely with the P- and N-domains. The binding of two Ca^{2+} ions from the cytoplasmic side of the membrane exerts a translational movement of the M4 helix resulting in a displacement of the A-domain, which enables a close interaction between the P- and N-domains cross-linked by ATP now interacting with the Mg^{2+} site and Asp 351 residue. This allows for phosphorylation of the enzyme forming the so-called adenosine diphosphate (ADP)-sensitive $\text{Ca}_2\text{E1}\sim\text{P}$ high-energy intermediate state which is accompanied by the occlusion of bound calcium at high-affinity sites. Phosphorylation of the ATPase unleashes the N-domain from the P-domain and induces a subsequent rotation of the A-domain, interacting now with the phosphorylated P-domain and manipulating the transmembrane segments M1 through M4 in formation of the ADP-insensitive E2P state. This, in turn, forces these helices to spread out and separate from segments M5 and M6 exposing a large water-filled opening, which provides a luminal exit pathway leading from the two, now deformed, Ca^{2+} binding sites in the membrane. Ca^{2+} ions are now released to the lumen from low-affinity sites that consequently adopt a high affinity for counter-transported protons (i.e., changing the pK_a to a higher value). Counter-cation binding stimulates the last step in the reaction cycle, namely the return of the pump to the E2 state by dephosphorylation. This reaction is mediated by hydrolytic cleavage of the aspartyl phosphoanhydride, enabled by a close interaction between the A- and P-domains that results in docking of the A-domain's TGES motif into the phosphorylation site. Here the Glu183 of the TGES motif activates a water molecule for in-line nucleophilic attack on the phosphorylation site. A total of two to three protons (depending on the pH and other environmental conditions) are counter-transported from the luminal to the cytosolic side of the membrane in this process, being released from the E2 state prior to the binding of Ca^{2+} . With two Ca^{2+} ions bound to the pump and no nucleotides present, the ATPase adapts a $\text{Ca}_2\text{E1}$ conformation that is characterized by a rather loose interaction between the three cytosolic domains, resulting from a counter-clockwise rotation of the A-domain around the P-domain upon the coordination of Ca^{2+} . It remains unsolved if this structural state of the pump is of functional importance.

The pump reaction cycle can be regulated on many levels, for example, by the presence of monovalent cations and by high concentrations of ATP or Ca^{2+} . As an example, the dephosphorylation reaction of the E2P state is facilitated by binding of a monovalent cation such as K^+ or Na^+ at the C-terminal site of the P-domain, which helps to stabilize the pump and causes a 20-fold increase of the dephosphorylation rate. Furthermore, high levels of ATP stimulate all partial reactions of the cycle by a so-called modulatory effect. Structures with modulatory ATP show that the nucleotide destabilizes interactions that characterize one state, enabling the transition to a subsequent state (Figure 2).

The Sodium–Potassium Pump

The Na^+,K^+ -ATPase maintains sodium and potassium gradients across the plasma membrane of animal cells by

Figure 2 Schematic overview of the functional cycle of the sarcoplasmic reticulum Ca^{2+} -ATPase.

transporting three Na^+ ions out of the cell in exchange for two extracellular K^+ ions. These gradients are necessary for energization of the resting potential, cell signaling, regulation of cell volume, osmotic activity and pH, and for cellular uptake of ions, nutrients, and neurotransmitters. Mutations in the brain Na^+, K^+ -ATPase lead to neurodegenerative disorders such as the migraine subtype familial hemiplegic migraine type 2 and the movement disorder familial rapid-onset dystonia parkinsonism.

Unlike the Ca^{2+} -pump, the Na^+, K^+ -ATPase is composed of three subunits denoted by α , β , and γ (Figure 3). The catalytic α -subunit performs ATP hydrolysis together with Na^+ and K^+ binding and its structure is homologous to the structure of the Ca^{2+} -ATPase, containing three cytoplasmic domains P, A, and N, and a membrane-embedded M-domain with 10 transmembrane spanning helices comprising the binding sites for Na^+ and K^+ . The β -subunit, consisting of one transmembrane-spanning helix and a large extracellular glycosylated domain, is a unique feature of the K^+ -counter-transporting-P-type ATPases – the Na^+, K^+ -ATPase and H^+, K^+ -ATPase. It is directly associated with the transmembrane helices M7 and M10 of the α -subunit covering the extracellular loops of the M5–M10 segment like a lid. The β -subunit is essential for the pump's activity as it is required for binding and occlusion of K^+ ions, for modulation of the pump's catalytic properties, and for stability of the catalytic α -subunit as well as its maturation and trafficking to the plasma membrane. Furthermore, there is evidence that in many cell types the $\alpha\beta$ -subunit complex is associated with a small tissue-specific regulatory γ -subunit from the FXYD protein family. This third subunit is not required for the function of the pump, but can affect its conformational state and the affinity for Na^+ , leading to a modulation of the Na^+, K^+ -ATPase activity. While the transmembrane part of the γ -subunit is within the interaction distance of the α -subunit's M-domain, its extracellular site containing the conserved FXYD motif moves in between the α - and β -subunits.

In humans, four different isoforms of the α -subunit and three isoforms of the β -subunit have been identified, denoted $\alpha 1$ – $\alpha 4$ and $\beta 1$ – $\beta 3$, respectively. These isoforms have different physiological roles, display different voltage sensitivities, and are tissue specific. While there are only very few differences between the four α isoforms in the transmembrane region, they

differ in surface-exposed regions of the A- and N-domains, which may reflect their characteristic interactions with other tissue-specific cellular components, for example, during trafficking. The most abundant form of the enzyme is the $\alpha 1\beta 1$ isoform, expressed in most tissue types. The $\alpha 2$ isoform is found mainly in the skeletal muscle, and also in the brain, heart, and eyes. The $\alpha 3$ isoform is mostly found in the brain and isoform $\alpha 4$ is expressed only in testis/sperm cells.

The overall architecture of the catalytic subunit of the Na^+, K^+ -ATPase is almost identical to the structure of the Ca^{2+} -ATPase, except for a slight shift in the N-domain. Also the conserved residues in the three cytoplasmic domains playing a role in phosphorylation and dephosphorylation are found in nearly the same positions in both pumps – for example, Asp 351, an aspartate residue that becomes phosphorylated during the SERCA 1a reaction cycle, corresponds to an Asp 369 residue in the Na^+, K^+ -pump. While the structure of the P-domain is highly similar in both pumps, the A- and N-domains of the Na^+, K^+ -ATPase are a few surface-loops residues shorter than in the Ca^{2+} -ATPase. As in the Ca^{2+} -ATPase, the M4 and M6 helices of the α -subunit of the Na^+, K^+ -ATPase are unwound in the middle, thereby making space for an ion-binding pocket exposing main chain carbonyls between transmembrane helices M4, M5, M6, and M8. Structural analyses clearly indicate that Na^+ is released on the extracellular side in exchange for K^+ being counter-transported to the cytoplasm through the same occlusion cavity, that is, as suggested by the consecutive transport model. Surprisingly, the structural resemblance of the α -subunit of the Na^+, K^+ -ATPase to the Ca^{2+} -ATPase is very high even in the cation-binding pocket, with only a few differences in the amino acid residues involved in the binding of ions, suggesting that subtle differences in the positions of the side chains and water molecules are contributing to the cation selectivity of the pump. In the membrane domain of the Na^+, K^+ -ATPase, significant differences from the Ca^{2+} -ATPase were observed in helices M7 and M10, and a unique aspect of the Na^+, K^+ -ATPase is the third Na^+ -binding site, whose exact location still remains unresolved.

The transport cycle of the Na^+, K^+ -ATPase resembles that of the calcium pump, starting with the binding of three intracellular Na^+ ions from the cytoplasmic side of the membrane to the E1 form that enables the phosphorylation of Asp 369 by ATP. This leads to a conformational change resulting in the E2P state, accompanied by the release of the three Na^+ ions into the extracellular environment. Subsequently, binding of two K^+ ions from the extracellular side triggers the dephosphorylation reaction, followed by a transition from the E2 to the E1 state that is accompanied by the release of the two K^+ ions into the cytoplasmic side of the membrane. The Na^+ and K^+ ions become temporarily occluded inside the binding pocket during the transport cycle.

The reaction cycle of the Na^+, K^+ -ATPase can be regulated by changes in the Na^+ and K^+ concentrations, through interactions with proteins from the FXYD family, and by hormonal regulation. Additionally, the C-terminus of the α -subunit has been shown to participate in Na^+, K^+ -ATPase regulation by controlling the affinity for Na^+ on both sides of the membrane and interacting with the third Na^+ -binding site.

The most widely studied inhibitors of the Na^+, K^+ -ATPase reaction cycle are cardiotonic steroids (also called cardiac

Figure 3 Crystal structures of the rabbit sarcoplasmic reticulum Ca^{2+} -ATPase, pig Na^+, K^+ -ATPase, H^+ -ATPase from *Arabidopsis thaliana* and Cu^+ -ATPase from *Legionella pneumophila*. Transmembrane helices are depicted in green, N-domain in red, P-domain in blue, and A-domain in yellow. glycosides), naturally found in many plants and secreted as toxins by several species of toads, snakes, or fireflies. These compounds have been used in the treatment of congestive heart failure for more than two centuries as they are able to cause a local increase in the intracellular Na^+ concentration, followed by a slowdown of the secondary active transport of Ca^{2+} out of the cell and a consequent increase of the contractility of the cardiac muscle. Recently, compounds derived from cardiotonic steroids have attracted attention also as anti-cancer drugs for breast cancer treatment. It has been shown that cardiotonic steroids interact with the extracellular part of the Na^+, K^+ -ATPase (preferably with its E2P conformation), most likely preventing the re-entry and occlusion of K^+ ions by blocking the extracellular cation exit pathway and stabilizing an E2P-like conformation that antagonizes K^+ binding.

The Gastric Proton–Potassium Pump

The gastric H^+, K^+ -ATPase is located in the secretory network within the gastric parietal cells of the stomach. It transports protons from the cytoplasm to the extracellular side of the membrane in exchange for K^+ ions, causing an acidification of the stomach that improves digestion and functions as a defensive mechanism against invasive bacteria. Interestingly, the gastric pump is the only member of the P-type

ATPase family with a variable counter-transport stoichiometry per ATP that is changing from 2:2 at pH 6.1 to 1:1 at a pH below 3.

Similarly to the overall structure of the Na^+, K^+ -ATPase, the H^+, K^+ -pump is composed of two subunits – a catalytic α -subunit with 10 transmembrane helices and a β -subunit with one transmembrane segment and six or seven N-linked glycosylation sites on the extracellular side that are required for assembly, maturation, and proper sorting of the pump. Due to the lack of a high-resolution crystal structure of the H^+, K^+ -ATPase, the exact location of the β -subunit remains elusive. It was proposed that the functional form of the gastric H^+, K^+ -ATPase is an oligomer composed of two α - and two β -subunits, where one $\alpha\beta$ -complex is in the E1 state and the second one in the E2 state.

In contrast to the Na^+, K^+ -ATPase, the N-terminal tail of the β -subunit of the gastric pump is in direct contact with the P-domain of the catalytic α -subunit. This may play a role in stabilizing the enzyme conformation and in preventing the reverse reaction of the transport cycle (i.e., the E2P to E1P transition), which enables the generation of large H^+ gradients across the gastric parietal cell membrane. Similarly to the Ca^{2+} - and Na^+, K^+ -ATPase, the ion-binding cavity of the H^+, K^+ -ATPase can be found between transmembrane segments M4, M5, M6, and M8. A lysine residue (Lys 791) on the fifth transmembrane segment seems to be important for the ion specificity of the pump.

The transport cycle of the H^+,K^+ -ATPase is very similar to that of the Ca^{2+} -ATPase, with the E1P to E2P transition being accompanied by the release of H^+ into the extracellular space (allowed by the reorientation of M4 and M6 helices) and by the binding of K^+ ions. Conversely, during the E2P to E1 transition, K^+ ions are transported into the cytoplasmic side of the membrane where new protons become bound to the pump, accompanied by two magnesium ions. There is evidence that the structural changes during the H^+,K^+ -ATPase transport cycle are somewhat smaller than changes during the reaction cycle of the Ca^{2+} -ATPase.

The H^+,K^+ -ATPase is directly involved in the onset of several diseases, including peptic ulcers and gastroesophageal reflux diseases. The most widely used agents in the treatment of these conditions are sulphur-containing benzimidazole derivatives forming a group of so-called proton pump inhibitors, represented by omeprazole as the most prominent member. These compounds are able to bind to the E2 conformation of the pump from the extracellular side of the membrane and, upon their activation by acidic pH, form disulphide bonds with cysteine thiol groups of the H^+,K^+ -ATPase. This results in the formation of an irreversibly inhibited complex as the pump remains trapped in an inactive E2P state where the re-entry of K^+ -ions from the luminal side of the membrane is blocked. Another group of the gastric pump inhibitors is formed by the potassium-competitive acid blockers, consisting of the Schering compound (SCH28080) and its derivatives. These compounds are able to noncovalently bind to the pump from the luminal side of the membrane in a reversible way, and act without the need of activation and thus in a much faster way than the proton pump inhibitors.

The Plasma Membrane Proton Pump

The plasma membrane H^+ -ATPase is found only in plants and fungi, where it acts as a functional analog of the Na^+ , K^+ -ATPase, energizing the plasma membrane potential and the secondary active transport systems. Although the Ca^{2+} -ATPase and the proton pump share only a low sequence homology, their overall structure is remarkably similar (Figure 3). The N-domain of the H^+ -ATPase is slightly smaller than that of the calcium pump, and analogously to the Asp 351 residue in the Ca^{2+} -ATPase, an Asp 329 becomes phosphorylated during the pump transport cycle. In contrast to other P-type ATPases, no counter-transport of ions has been observed in the H^+ -ATPase. On the basis of a crystal structure of the proton pump from *Arabidopsis thaliana* [8], a mechanism for proton binding has been proposed, consisting of a proton-binding site buried between the transmembrane segments M2, M4, and M6 featuring also an aqueous cavity. The proton specificity of the H^+ -ATPase is maintained by a protonated aspartate paired with an asparagine residue (Asp 684 and Asn 106) from the membrane domain.

Heavy Metal P-Type ATPases

P-type ATPases from subfamily I are involved in the homeostasis of heavy metals such as copper or zinc, and can also transport nonphysiological substrates such as Ag^+ , Cd^{2+} , or

Pb^{2+} . In contrast to other members of the P-type ATPase family, heavy metal pumps have only six to eight transmembrane helices and a smaller A-domain (Figure 3). Their characteristic feature is the presence of several cytosolic and transmembrane N- or C-terminal metal-binding domains that are required for phosphorylation and account for the substrate specificity, trafficking of the pump, and regulation of its functional cycle. Copper transporting P-type ATPases (subgroup IB-1) are the most widely studied heavy metal ATPases as their mutation impairs copper homeostasis and results in the onset of several neurodegenerative disorders such as Parkinson's, Alzheimer's, and prion-related diseases or the genetically inherited Menkes and Wilson diseases.

Flippases

Members of the P-type ATPase subfamily IV are called flippases because they are involved in the translocation of phospholipids (such as phosphatidylserine and phosphatidylethanolamine) from the exoplasmic to the cytoplasmic leaflet of membrane bilayers. This maintains the physiologically important asymmetric distribution of lipids across the membrane, necessary, for example, for the formation of new lipid vesicles and for membrane trafficking. While the substrate-binding domain of other P-type ATPases contains cation-interacting amino acid residues, transmembrane helices M4 and M6 in flippases have hydrophobic amino acid residues that can interact with hydrophobic moieties of phospholipids. Mutations in human flippases are associated with severe liver diseases such as the Byler disease.

Glossary

Iron–sulfur clusters Ensembles of iron and sulfur which can be oxidized or reduced through the donation or acceptance of electrons. Within complex I, only two forms are found: either 4Fe–4S or 2Fe–2S.

Quinone (Q) A hydrophobic molecule containing a conjugated ring structure at one end and a tail from several isoprenoid units. These compounds act as electron

acceptors/donors between several of the respiratory complexes.

Reactive oxygen species (ROS) Highly reactive oxygen molecules due to the presence of an unpaired electron. These molecules have a role in signaling and also cause damage to a cell through reactions with biological molecules.

Thermus thermophilus A Gram-negative extremely thermophilic bacteria which has optimal growth at around 70 °C.

Introduction

Complex I (NADH:ubiquinone oxidoreductase, EC 1.6.5.3) is the first enzyme of the mitochondrial and bacterial respiratory chains. It catalyzes the transfer of two electrons from nicotinamide adenine dinucleotide reduced form (NADH) to quinone (Q), coupled to the translocation of four protons (current consensus value) across either the mitochondrial inner or bacterial cytoplasmic membrane according to the equation: $\text{NADH} + \text{Q} + \text{H}^+ + 4\text{H}^+_{\text{in}} \rightarrow \text{NAD}^+ + \text{QH}_2 + 4\text{H}^+_{\text{out}}$ (where ‘in’ corresponds to the mitochondrial matrix or the bacterial cytoplasm and ‘out’ corresponds to the mitochondrial or the bacterial intermembrane space). This produces nicotinamide adenine dinucleotide (NAD^+), which is used to regenerate NADH, and quinol, which is used as a substrate by other complexes in the respiratory chain. In completing this reaction, complex I contributes approximately 40% of the proton-motive force required for the generation of adenosine triphosphate (ATP) by ATP synthase. Different quinones are used as electron acceptors by complex I from different species. The mitochondrial enzyme uses ubiquinone, complex I from *Thermus thermophilus* uses menaquinone, and the complex in *Escherichia coli* uses either ubiquinone or menaquinone, depending on the growth conditions. Mutations in various complex I subunits lead to many human neurodegenerative diseases. Complex I has also been implicated as a source of reactive oxygen species (ROS) within the mitochondria. This is caused by electron leak during complex I turnover and ROS production increases when the enzyme is inhibited. ROS can damage mitochondrial DNA and may be one of the causes of aging. The sporadic form of Parkinson’s disease may, in part, be caused by an increase in ROS due to malfunctioning complex I.

Overall Organization

Mitochondrial complex I is one of the largest known membrane complexes. Bovine complex I consists of 45 different subunits with a combined mass of about 980 kDa. The prokaryotic enzyme is much simpler, with a total mass of around 550 kDa, and consists of about 14 subunits conserved from

bacteria to humans. Both the mitochondrial and prokaryotic enzymes contain a core of eight iron–sulfur clusters (six 4Fe–4S and two 2Fe–2S) and a noncovalently bound flavin mononucleotide (FMN). Based on the conservation of core subunits and prosthetic groups, the prokaryotic enzyme can be considered a minimal model of the larger eukaryotic enzyme. The overall structure of the enzyme has been analyzed in various species by electron microscopy, revealing that complex I is L shaped and consists of two arms. The hydrophilic peripheral arm contains conserved subunits Nqo1–6 and 9 (*T. thermophilus* nomenclature, which will be used throughout for simplicity) and the hydrophobic membrane arm contains Nqo7–8 and Nqo10–14. The membrane arm is embedded within the lipid bilayer and the hydrophilic arm protrudes almost perpendicular from the membrane into the bacterial cytoplasm (or mitochondrial matrix). The NADH-binding site, FMN, and all iron–sulfur clusters are found within the hydrophilic arm. The nomenclature of equivalent subunits in bovine and *E. coli* complex I is shown in Table 1, as are the locations of the prosthetic groups.

The X-ray crystal structure of the hydrophilic arm of complex I from *T. thermophilus* has been determined at 3.1 Å resolution, in both the oxidized and reduced, NADH-bound, forms. These structures revealed the organization of different subunits and identified the spatial location of the redox centers (Figure 1). In *T. thermophilus*, the hydrophilic arm contains eight subunits: Nqo1–6, Nqo9 and, unexpectedly, an additional subunit, which is not part of the *Nqo* operon, Nqo15.

Overall, the hydrophilic domain of *T. thermophilus* complex I is Y shaped, which is consistent with recent electron microscopy (EM) reconstructions of the complex from *Yarrowia lipolytica*, *Aquifex aeolicus*, and bovine, suggesting a high level of structural conservation within this enzyme. Subunits Nqo4 and Nqo6 form the bottom of the structure, where they interface with the hydrophobic domain and form part of the quinone-binding site. The NADH/FMN-binding site is located in subunit Nqo1 at the top of the enzyme, some 100 Å from Nqo4 and Nqo6. Electron transfer between the two substrate-binding sites occurs via the chain of iron–sulfur clusters (Figure 1). The complex appears to have evolved from several smaller subcomplexes, or building blocks. Subunit Nqo2 is related

to thioredoxins, Nqo9 to ferredoxins, the N-terminus of Nqo3 to FeFe-hydrogenases, the C-terminus of Nqo3 to molybdopterin-containing enzymes, and Nqo4 and Nqo6 to NiFe-hydrogenases. Larger building blocks can be traced to NAD⁺-reducing hydrogenases (subunits Nqo1–3) and membrane-bound hydrogenases (subunits Nqo4–6 and 9 plus most of the membrane domain subunits).

The lack of structural information on the hydrophobic domain means less is known about its organization. Fragmentation studies have shown that directly below Nqo4 and Nqo6

of the hydrophilic arm, subunits Nqo7, Nqo8, Nqo10, and Nqo11 form a bundle which has been implicated in quinone binding. Subunits Nqo12, Nqo13, and Nqo14 are toward the distal end of the hydrophobic domain, with Nqo12 the furthest away from the hydrophilic arm. These subunits share sequence similarity with Na⁺ or K⁺/H⁺ antiporters of the Mrp family. This homology suggests that these three subunits are involved in pumping protons across the membrane. As Nqo12, Nqo13, and Nqo14 are some distance away from the quinone-binding site, conformational changes are likely to be necessary during catalysis to link electron transfer down the hydrophilic arm to proton pumping in the distal end of the hydrophobic arm.

Table 1 A list of the conserved subunits present in *T. thermophilus* and *E. coli* complex I and their equivalents in bovine complex I (the prosthetic groups present in each subunit are also listed, where an N prefix designates an iron–sulfur cluster)

<i>T. thermophilus</i>	<i>E. coli</i>	Bovine	Prosthetic group
Nqo1	NuoF	51 kDa	FMN, N3
Nqo2	NuoE	24 kDa	N1a
Nqo3	NuoG	75 kDa	N1b, N4, N5, and in some species N7
Nqo4	NuoD – fused with NuoC	49 kDa	
Nqo5	NuoC – fused with NuoD	30 kDa	
Nqo6	NuoB	PSST	N6a, N6b
Nqo7	NuoA	ND3	
Nqo8	NuoH	ND1	
Nqo9	NuoI	TYKY	N2
Nqo10	NuoJ	ND6

Nqo12	NuoL	ND5	
Nqo13	NuoM	ND4	
Nqo14	NuoN	ND2	

Hydrophilic Domain and Redox Centers

Structures of the hydrophilic arm revealed the arrangement of all the known redox centers within the enzyme: the FMN and nine iron–sulfur clusters. (There are proposals that the membrane domain contains one or two bound quinone molecules acting as cofactors, but this idea has not been confirmed experimentally.) Electrons are passed down the iron–sulfur cluster chain from the substrate NADH to a quinone molecule in the vicinity of cluster N2. The arrangement of the clusters suggests a likely electron path, as the edge-to-edge distance between the redox centers should be within 14 Å for biologically significant rates of electron transfer. Seven of the Fe–S clusters form a connecting redox chain between the FMN and the quinone-binding site (Figure 1). Two electrons enter the complex from one NADH molecule, which has a midpoint redox potential of –320 mV at pH7, and are transferred as a hydride to FMN (midpoint potential –340 mV), which resides in subunit Nqo1. One electron is then transferred from FMN to a nearby

Figure 1 An overview of the structure (PDB 2FUG). (a) Side view, with the membrane arm likely to be beneath and extending to the right, in the direction of helix H1. Each subunit is colored differently; FMN is shown as magenta spheres, Fe atoms as red spheres and S atoms as yellow spheres. Helix H2 is shown in olive. (b) A view rotated by 180°, showing a model of a likely mode of attachment of the peripheral domain to the membrane domain. The outline of intact *E. coli* complex I comes from single particle analysis, and the model of subunit arrangement is derived from fragmentation studies. Numbers indicate hydrophobic Nqo subunits. (c) Arrangement of redox centers. The overall orientation is similar to that in (a). The main pathway of electron transport is indicated by blue arrows and a diversion to cluster N1a by a green arrow. The distances between the centers given in Å were calculated both center-to-center and edge-to-edge (shown in parentheses).

tetranuclear cluster N3, also located in Nqo1. From N3 the electron is passed to the binuclear cluster N1b and then on to tetranuclear clusters N4 and then N5, all coordinated within Nqo3. From N5 the electrons are transferred to the two tetranuclear clusters in Nqo9, N6a, and N6b, before being passed to the final tetranuclear cluster, N2, within Nqo6. N2 has the highest midpoint potential of the clusters (~ -100 mV) and passes its electron onto the quinone substrate, ubiquinone (+110 mV) or menaquinone (-80 mV), depending on the organism. Most of other electron paramagnetic resonance (EPR)-visible clusters in complex I have potentials around -250 mV, but several clusters are EPR silent and may have potentials below -400 mV. Despite its length, this redox chain is very efficient – EPR experiments on freeze-quenched samples have shown that first electron from NADH arrives at N2 within $90 \mu\text{s}$, close to the theoretical limit. Although the exact site of quinone binding is still under debate, cluster N2 lies only $10 \text{ \AA}$ from a likely quinone-binding channel formed between Nqo6 and the adjacent Nqo4 subunit (Figure 1). An additional tetranuclear cluster N7 is present in Nqo3 in *T. thermophilus* but with $20 \text{ \AA}$ between this cluster and its closest neighbor, N4, it is too removed from the redox chain to be part of the electron transfer pathway. As cluster N7 is also only conserved in a small number of bacterial species, it may represent an evolutionary remnant from molybdopterin-containing enzymes.

Binuclear cluster N1a, within subunit Nqo2, is fully conserved but it does not form part of the main redox chain (Figure 1). However, it is within electron transfer distance from the flavin ($12 \text{ \AA}$). This cluster has a midpoint potential lower than the other clusters at -370 mV (in bovine enzyme, the best studied example). This would make it unlikely to accept the first electron from fully reduced FMNH_2 , but it may accept an electron from flavosemiquinone, with its lower potential, after the first electron from FMNH_2 is donated to N3. When the downstream electron transfer chain is ready to accept the second electron (probably after quinone reduction), the electron on N1a could then be returned to the FMN moiety and then passed to N3 and down the redox chain. This mechanism would preclude a flavosemiquinone intermediate from existing for any significant period of time, as the two electrons from NADH could be passed from FMN to N1a and N3 almost simultaneously. This would reduce the prevalence of a reaction of the flavosemiquinone intermediate with oxygen leading to damaging ROS production at the solvent-exposed flavin site. As the likely rate-limiting step of the complex I reaction is the reduction of quinone, most iron-sulfur clusters would remain reduced during catalysis, which may promote flavosemiquinone production. This would make N1a's role as an electron storage cluster essential, as it is shielded from the solvent.

Frataxin-Like Subunit in Complex I

An unexpected finding from the structure of the hydrophilic domain of *T. thermophilus* complex I was the presence of an additional subunit, Nqo15. This protein is not part of the *Nqo* operon and so far its homologs have only been identified in a few extremophilic prokaryotic species. One possible

role for this subunit could be to stabilize the structure of the hydrophilic arm, as it is rather narrow in the middle and Nqo15 interacts with many subunits in this area. Unexpectedly, the fold of Nqo15 is nearly identical to that of frataxin, despite very low sequence homology ($\sim 11\%$ identity). Frataxin is involved in the biogenesis of iron-sulfur clusters in mitochondria and bacteria, although its exact role is still under debate. It interacts with the Isc machinery, possibly by delivering iron, and may have a role in iron storage. The *T. thermophilus* genome contains no other, sequential homolog to frataxin, but the Isc genes are present. As Nqo15 is not incorporated into the *Nqo* operon, this protein might have a double role in *T. thermophilus* – as part of complex I and as frataxin analog in the cytoplasm.

The Nqo15 and frataxin fold consists of a six-stranded antiparallel β -sheet with two α -helices on one face of the β -sheet. Nqo15 interacts with the rest of the complex mainly via the other exposed face of the β -sheet. This face of the β -sheet is also suggested to be involved in interactions of frataxin with its protein partners. *T. thermophilus* complex I provides the first example of the frataxin-like protein permanently bound to its partner and so may illustrate a mode of such interaction.

Frataxins contain several fully conserved acidic residues on the edge of the first β strand and α -helix and these residues are proposed to be involved in iron binding. Some of these residues are not present within Nqo15, suggesting it may not bind metal ions in the same manner. However, Nqo15 has a series of four histidine residues along one face of the fifth β strand. Within *T. thermophilus* complex I, these histidines face a channel formed between subunits Nqo1, 2, 3, and 15 (Figure 2). The side chains of several conserved histidines and glutamates from Nqo1–3 also face into this channel, forming at least two potential metal-binding sites. Divalent cations, including manganese, a close mimic of iron, were identified as bound inside this channel in the hydrophilic arm structures

(Figure 2). As the end of this channel lies in close proximity to the iron–sulfur clusters N1a and N3 (~ 10 Å), this leads to the intriguing possibility that Nqo15 may be involved in iron binding, akin to frataxin, and have a role in the regeneration of these clusters. They are the nearest to the FMN, a known source of ROS, and so may be the first to be damaged during turnover.

NADH Binding

The determination of the structures of the ligand-free oxidized and NADH-bound reduced forms of *T. thermophilus* complex I hydrophilic domain allowed comparisons to be made between the structures. The substrate NADH binds in the cavity within subunit Nqo1 at the top of the hydrophilic arm, adjacent to the FMN moiety (Figure 3). Complex I does not contain a classical Rossmann nucleotide-binding fold and instead has a modified fold which binds both FMN and NADH through the incorporation of an additional glycine-rich loop. The FMN/NADH-binding pocket is highly conserved with the residues involved in interactions with both of the cofactors retained between species as varied as bacteria and humans.

Within the binding pocket, the nicotinamide ring of NADH stacks against the exposed face of the isoalloxazine ring of the FMN moiety, in a manner similar to that seen in other nucleotide-binding flavoenzymes (Figure 3). This positions the B-face of the nicotinamide ring against the *re*-face of the isoalloxazine ring allowing the 4B hydrogen of NADH to transfer as a hydride to the N5 atom of FMN. The transfer of the hydride is fast in complex I, and the distance between these two atoms is slightly shorter than usual, at 3.2 Å. The short distance between the two nucleotides may be caused by the close proximity of the C β atom of Nqo1 Glu97, which is within van der

Waal's contact distance with the C4N atom of the bound NADH, forcing the two nucleotides together.

Upon binding of NADH, a shift of around 1.5 Å in the loop formed by Nqo1 residues 202–207 toward the bound NADH is observed. This positions the side chain of Phe205 1.7 Å closer to the adenine ring, promoting a stacking interaction, and a hydrogen bond forms between the side chain of Lys202 and the phosphate moiety of the NADH molecule. Further stacking interactions are formed with Phe70 and Phe78. Complex I, compared to other dehydrogenases, is unusual in its ability to use deamino-NADH as a substrate. This is due to the relatively open NADH-binding pocket in which N6A of the adenine ring (which is an oxygen in deamino-NADH) forms no interactions with the protein.

Overall, there are no large-scale changes in the rest of the structure upon reduction by NADH. However, reproducible shifts of around 1 Å can be seen in a 4-helix bundle in Nqo4 (residues 110–297) and helices H1 and H2 in Nqo6 (residues 18–35 and 143–160). Due to the proximity of these structural elements to the membrane domain, these movements may be propagated into the membrane arm and form part of the catalytic cycle, eventually resulting in proton pumping. Also, the number of close contacts between subunits is decreased by about 7–8% upon reduction, indicating slight loosening of the structure. This is consistent with the decreasing number of cross-links between subunits, observed upon reduction of complex I from several species. Without the structure of the whole complex it is difficult to draw firm mechanistic conclusions. However, a similar degree of change in cross-linking patterns upon reduction was observed both for the intact complex and for the isolated hydrophilic domain. As the middle part of the hydrophilic domain (between NADH and quinone-binding sites) does not undergo any conformational changes, it is likely that observed shifts of Nqo4/Nqo6 helices are driven by changes in the redox state of the nearby clusters (N2 and N6a/b).

A surprising result was seen when comparing the coordination of the terminal iron–sulfur cluster N2 in the oxidized and reduced crystal structures. N2 is coordinated by an unusual tandem cysteine motif consisting of consecutive Cys45 and Cys46 from Nqo6, with Cys111 and Cys140 completing the ligation (Figure 4). The tandem cysteine motif is fully conserved in complex I and so is likely to be important for its function. The structure revealed strained geometry in the side chains of these residues. In the oxidized form of the enzyme, clear electron density was observed for both the side chains of Cys45 and Cys46 (Figure 4(a)). Upon full reduction of the hydrophilic domain by NADH, the electron density for the side chain of Cys46 disappears, suggesting that this residue has disconnected from the cluster (Figure 4(b)). However, when crystals of the hydrophilic domain were partially reduced with dithionite, the electron density for the side chain of the neighboring cysteine, Cys45, was absent and the side chain of Cys46 had clear connecting density to the cluster (Figure 4(c)). Similar coordination was observed in crystals reduced by NADH but exposed to air for longer period before cryo-cooling – it is likely that in both cases some of the clusters upstream were oxidized, while N2 remained reduced due to its higher potential (as observed by EPR under similar conditions). Thus, upon reduction of N2 one of the tandem cysteines is disconnected,

Figure 3 The NADH- and FMN-binding site. The site is viewed from the solvent-exposed side. FMN and residues involved in NADH binding are shown as sticks with carbon in yellow and NADH with carbon in salmon. Hydrogen bonds are shown as dotted lines in green, stacking interactions in gray, and hydride transfer path in red. Van der Waal's contact between 1Glu97 and C4N of NADH is shown in gray. Prefixes before residue names indicate the subunit number.

Figure 4 The coordination of iron–sulfur cluster N2 within Nqo6 by Cys45, Cys46, Cys111, and Cys140. The side chains of the adjacent residues Cys45 and Cys46 both ligate the cluster in the oxidized state (a), causing their side chains to have a strained geometry. In the structure of the NADH-reduced state (fully reduced redox chain), the side chain of Cys46 appears disconnected (b), whereas in the structure of the dithionite-reduced state (redox chain partially reduced, including cluster N2), the side chain of Cys45 is disconnected (c).

the choice being dependent on the redox state of neighboring clusters (N6a/b). It is likely that the disconnected cysteine side chains become protonated and that N2 is instead ligated by a solvent molecule (water or OH, akin to aconitase). This is consistent with the well-known redox-Bohr effect – the midpoint redox potential of cluster N2 is pH dependent, that is, it (or nearby side chain) becomes protonated upon reduction. These results suggest that the coordination of N2 is changed when it is reduced and it is possible to envisage that Cys45 and Cys46 are becoming sequentially disconnected from N2 and protonated, before passing their protons on to the bound quinone molecule. The possible mechanism may involve both protonation/de-protonation of tandem cysteines and conformational coupling, propagating movements of the 4-helix bundle in Nqo4 and helices H1 and H2 in Nqo6 into the membrane domain. The unusual coordination by tandem cysteines may also play a role in these conformational changes by providing protein flexibility in the vicinity of cluster N2.

Mutations in Complex I Subunits

Numerous mutations in complex I have been implicated in human diseases. The determination of the structure of the hydrophilic arm from *T. thermophilus* enabled mapping of these mutations onto the structure and allowed identification of their possible role in catalysis. In general, disease-causing mutations are in regions around the substrate-binding pockets, iron–sulfur clusters, or the interface with the hydrophobic domain. The mutations lead to a variety of phenotypes which can be classified as resulting in reduced NADH dehydrogenase activity, reduced complex I levels in the cell, instability of complex I, change in affinity to quinone or sensitivity to quinone-site inhibitors, or altering the properties of iron–sulfur clusters. All of these effects reduce the efficiency of complex I. One such example is the mutations of Y204C and C206G in the 51 kDa subunit in humans (Nqo1 in *T. thermophilus*). These mutations result in only 18% of complex I activity remaining and cause hypotonia, ataxia, and infant death. The mutations can be mapped to Tyr180 and Cys182 in Nqo1, which are both adjacent to the nucleotide-binding sites. In fact, Tyr180 forms a hydrogen bond with Glu97, which is involved in promoting interactions between

NADH and FMN (Figure 3). Mutations in either of these residues would then be likely to have an effect in binding of the substrate NADH to the enzyme. Another example is the mutation of Leu231 to a valine in the human 75 kDa subunit (Nqo3), where only 25% of complex I activity remains, leading to Leigh syndrome and infant death. Leu231 is equivalent to Leu235 in Nqo3 and is directly facing cluster N4, so any mutation in this region is likely to evoke either structural or redox changes in the cluster.

Supernumerary Subunits in Eukaryotic Complex I

Bovine complex I has been shown to contain 45 subunits, with the seven core hydrophobic subunits encoded within the mitochondria and all other subunits encoded in the nucleus. Apart from the core 14 subunits, which have equivalents in the bacterial enzyme, little is known about the roles of the supernumerary subunits in higher eukaryotic complex I. No additional prosthetic groups have been detected in the supernumerary subunits; however, several of these subunits have been implicated in diseases in humans. For example, in human complex I, a splice mutation in NDUFA11 causes encephalomyopathy, and a 5 base pair (bp) duplication eliminating a phosphorylation site in NDUF54 resulted in Leigh-like symptoms due to a deficiency in complex I. Several subunits are homologous to other proteins with known functions, but it is not clear what role they play in complex I. Many smaller subunits classify as single transmembrane domain proteins and may assist in assembly and stability of the membrane domain. The total number of these so-called supernumerary subunits was only finalized recently and further work is required to understand how these subunits affect the function of complex I.

Conclusion

The recent work on the hydrophilic domain from *T. thermophilus* has provided the first structural information on the organization of eight core subunits and nine iron–sulfur clusters. It has identified the electron transfer pathway down a series of seven of the iron–sulfur clusters from the FMN site to a quinone site at the interface with the hydrophobic domain. Analyses of the

structures of the reduced NADH-bound enzyme have defined the mode of NADH binding and revealed unexpected changes in the coordination of the terminal iron–sulfur cluster N2, which are likely implicated in the mechanism. Comparisons of the sequences of complex I have allowed several disease-causing mutations in the human enzyme to be explained through analysis of the structure. However, the structure of the hydrophilic arm is only part of the story and we wait with bated breath for the full structure to become available and provide further insight into the mechanism of this remarkably complex enzyme.

Glossary

Haldane relationship An equation relating the equilibrium constant to the kinetic constants of an enzymatic reaction.

Isotope effect The effect of isotopic substitution, expressed as the ratio of the parameter for the light isotope to that for the heavy one.

Michaelis constant The concentration of a substrate that gives half of the maximum velocity of an enzymatic

reaction. It is the apparent dissociation constant in the steady state.

Substrate A molecule that is converted to a product during an enzyme-catalyzed reaction.

Turnover number The number of substrate molecules converted to product per enzyme molecule per unit time. The units are usually reciprocal seconds.

Enzymes catalyze reactions by forming complexes with their substrate(s), accelerating the chemical reaction by lowering the activation energy for the reaction, and then releasing the product(s). The enzyme has to have sufficient affinity for a substrate to form a complex with it at the physiological concentration of this molecule. Conversely, however, too great an affinity for the substrate usually results in too great an affinity for the product, so that product release becomes rate limiting. The maximum rate of an enzyme-catalyzed reaction is limited, in fact, by the relationship between the equilibrium constant and the kinetic constants called the Haldane relationship, and one element of this restriction is the affinity of the substrate.

The Haldane Relationship

As mentioned above, the Haldane relationship allows calculation of the maximum rate of an enzyme-catalyzed reaction. For the simple conversion of substrate A into product P, the initial rate of the forward reaction in the absence of P is

$$v_f = -d[A]/dt = V_1[A]/(K_a + [A]) \quad [1]$$

and that in the back reaction is

$$v_r = -d[P]/dt = V_2[P]/(K_p + [P]) \quad [2]$$

where V_1 and V_2 are maximum velocities in forward and reverse reaction, respectively, and K_a and K_p the Michaelis constants for A and P (i.e., apparent dissociation constants in the steady state).

The Haldane for this mechanism is the ratio of the V/K values in forward and reverse directions:

$$K_{eq} = [P]_{eq}/[A]_{eq} = (V_1/K_a)/(V_2/K_p) = V_1K_p/(V_2K_a) \quad [3]$$

With units of reciprocal time, is the apparent first-order rate constant for reaction at low substrate concentration, so eqn [3] is analogous to the one for a nonenzymatic reaction where K_{eq} would equal k_1/k_2 , that is, the ratio of rate constants in forward and reverse directions.

To optimize the turnover number of an enzyme (V_1/E_t) in this case, also known as k_{cat} , with units of reciprocal time, we can raise the two V/K values in constant ratio until one

V_1/K_a value (with units of $M^{-1}s^{-1}$) reaches the limit set by diffusion. V_1/K_a (or k_{cat}/K) is a second-order rate constant for productive combination of enzyme and substrate and subsequent reaction to give product, and the combination of enzyme and substrate can only go as fast as these two can diffuse together. This limit is $\sim 10^9 M^{-1}s^{-1}$ for small substrates, and somewhat less for larger ones like adenosine triphosphate.

Once the V_1/K_a value in eqn [3] is as high as it can go, the only way to increase V_1/E_t is to increase K_a as well. But K_a cannot exceed the physiological level of A, or the enzyme will not be at least half saturated. Thus, V_1/E_t has an upper limit, and enzymes that are part of metabolic pathways are optimized to operate at this limit. The actual turnover numbers vary, depending on K_{eq} and the physiological level of the substrate, but evolution has brought these enzymes to the limit set by the Haldane relationship. On the other hand, enzymes that are involved in control, as opposed to ones in metabolic pathways, often sacrifice speed for control characteristics, and do not have turnover numbers at the Haldane limit.

Catalysis

The catalytic process on an enzyme starts once the substrate is bound. As mentioned above, the enzyme has to have sufficient affinity to bind the substrate at its physiological concentration. The enzyme then has to lower the activation energy of the reaction sufficiently for it to go at a rate approaching the maximum given by the Haldane relationship. It is commonly said that the enzyme accomplishes this by binding the transition state structure more tightly than the ground state of the substrate, but this is really a definition of catalysis. Molecules resembling the transition state structure are often bound much more tightly than the substrate (see entry on transition state analogs). This is either because the geometry of the transition state is a better fit, or includes inherently tighter interactions (stronger hydrogen bonds, for example). Alternatively, the differential binding results because the substrate is destabilized when it is bound (sterically deformed, placed in an unfavorable electrostatic environment, etc.), but this destabilization is relieved in the transition state. Of course,

destabilization in one part of the substrate must be matched by tight binding in another part, or the substrate will not have sufficient affinity for the enzyme at its physiological level. Orotidine monophosphate (OMP) decarboxylase is a classic example, where a substrate analog with $-\text{COO}^-$ replaced by $-\text{O}^-$ binds 10^5 -fold more tightly to the enzyme. The difference is ascribed to charge repulsion between the carboxyl group of the substrate and an aspartate on the enzyme.

Free-Energy Profiles

The energetics of what happens during an enzymatic reaction is illustrated by a free-energy profile. **Figure 1** shows the free-energy profile at equilibrium for the nonenzymatic reaction of A to P. The activation energy, $\Delta G^\ddagger$, corresponds to the height of the barrier, and ΔG for the reaction ($= -RT \ln K_{\text{eq}}$) is the difference between the levels marked A and P. For a corresponding enzymatic reaction, one must decide what levels of A and P to use. **Figure 2** shows an equilibrium free-energy profile where the concentration of A is above its dissociation constant, so that the formation of EA has an equilibrium constant greater than unity, but where P is less than its dissociation constant, so that EP dissociation is favorable. $\Delta G^\ddagger$ is given by the height of the barrier above the level of EA, not E + A. The turnover number (V/E_t or k_{cat}) is determined by $\Delta G^\ddagger$.

If one picks different levels of A or P, the difference between E + A and EA, or E + P and EP, will differ as shown in **Figure 3**. The dissociation level of A (K_{ia}) is convenient, but then the level of P is determined by K_{eq} if an equilibrium free-energy profile is plotted, and will not usually match K_{ip} , its dissociation constant. Free-energy profiles may, of course, be plotted for nonequilibrium concentrations of reactants, but in any case it is critical to state the concentrations of reactions that are assumed in plotting the profile. When there are two or more substrates or products involved in the reaction, one must pick

Figure 1 Free-energy profile at equilibrium for an uncatalyzed reaction. $\Delta G^\ddagger$ is the activation energy and $\Delta G = -RT \ln K_{\text{eq}}$, the energy difference between product and substrate.

suitable levels of all reactants (and state them!) in order to plot a free-energy profile.

So far, we have considered only simple free-energy profiles with a single transition state connecting EA and EP. In practice, enzymes have different conformations at the various stages of the catalytic cycle. Thus, they have open forms where the reactants are free to bind and dissociate, and closed forms in which catalysis takes place. The chemistry may also take place in more than one step, so that intermediates are present. **Figure 4** shows a profile where a conformation change converts the open EA form to a closed, precatalytic EA^* form. This undergoes a catalytic reaction to give an EI intermediate complex, which then is further converted to the closed EP^* form. A final conformation change gives the open EP form, from which P can dissociate.

Rate-Limiting Step for V/K

The two independent kinetic constants for an enzymatic reaction are the maximum velocity, V , and the ratio of V and the Michaelis constant, V/K . There is a separate V/K for each substrate. Each of these parameters varies separately with pH, ionic strength, temperature, and the concentrations of other substrates, products, or inhibitors. The Michaelis constant, K , while it measures the apparent dissociation constant of the

Figure 2 Free-energy profile at equilibrium for an enzymatic reaction. The symbols have the same meaning as in **Figure 1**.

Figure 3 Free-energy profile showing the difference in the levels of (E + A) or (E + P) as the concentrations of A or P are changed. K_{ia} and K_{ip} are the dissociation constants of A from EA and of P from EP.

Figure 4 Free-energy profile showing conformation changes in the EA and EP complexes, as well as an intermediate between the two activated complexes. The levels of (E + A) and (E + P) are not shown.

substrate in the steady state, is not an independent constant, but just the ratio of V and V/K . Thus, when one speaks of 'rate-limiting steps' one must specify whether one is referring to V or V/K .

The rate-limiting step for V/K is the one with the highest barrier in the free-energy profile. V/K involves the combination of enzyme and substrate and reaction through the first irreversible step, which normally is release of the first product. Later steps that involve further conformation changes in the enzyme and release of other products do not affect V/K . Thus, the slow release of nicotinamide adenine dinucleotide from dehydrogenases, which often limits the maximum velocities of these enzymes, has no effect on V/K . As a result, the V/K value often is limited more by the chemistry of the reaction than V , and isotope effects on the chemistry are more fully expressed. Except for some slow mutants, full rate limitation by the chemical reaction is unusual, however, and the conformation changes that precede and follow the chemical reaction are usually partly rate limiting. The equation for an isotope effect on V/K is

$$^x(V/K) = (^xk + c_f + ^xK_{eq}c_r)/(1 + c_f + c_r) \quad [4]$$

where x defines the isotope effect (D, T, ^{13}C , ^{15}N , ^{18}O) and the leading superscript indicates the ratio of the parameters for light and heavy isotopes. xk is the intrinsic isotope effect on the chemical step and $^xK_{eq}$ the equilibrium isotope effect on the reaction. The constants c_f and c_r are forward and reverse commitments to catalysis, respectively, and are the ratio of the rate constant for the isotope-sensitive step to the net rate constant for release from the enzyme of either the substrate (for c_f) or the first product (for c_r). For the simple mechanism

$$c_f = (k_5/k_4)(1 + k_3/k_2) \quad c_r = (k_6/k_7)(1 + k_8/k_9) \quad [6]$$

The commitments, thus, consist of partition ratios of intermediates and these ratios correspond to the differences in barrier heights in a free-energy profile. In the profile shown in Figure 4, c_f and c_r will be small if the isotope effect measured involves reaction of EI to EP* because the barrier between EI

and EP* is the highest one. But if the isotope effect measured is on reaction of EA* to EI, c_f will be small, but c_r will be large. Thus, one will see largely the equilibrium isotope effect, as the EA* to EI step approaches equilibrium.

In the definition of c_f in eqn [5], k_5/k_4 is the internal part of the commitment (c_{f-in}) and $k_3k_5/(k_2k_4)$ is the external part (c_{f-ex}). A sticky substrate is one where the net rate constant for reaction of the initial collision complex to give products is faster than the rate constant for dissociation (k_2). This ratio is called the stickiness ratio (S_r) and is given by $S_r = c_{f-ex}/(1 + c_{f-in} + c_r)$ in terms of the parameters of eqn [5].

Rate-Limiting Steps for V

The rate-limiting step for the maximum velocity depends on the definition of rate limiting. One definition is the 'slowest' step, or the one with the highest individual barrier in the forward direction. Another definition is the 'least-conductive' step, which is the one that sees the highest total barrier to reach an irreversible step. A third definition is the most-sensitive step. This is the one that causes the greatest percentage change in the turnover number for a given percent change in the forward rate constant. An isotope effect on this step is more fully expressed than one on any other step. The isotope effect on V for mechanism 3 is

$$^xV = (^xk + c_{vf} + ^xK_{eq}c_r)/(1 + c_{vf} + c_r) \quad [7]$$

where xk , $^xK_{eq}$, and c_r have the same meaning as in eqn [5], but

$$c_{vf} = [k_3k_5/(k_3 + k_4)][1/k_3 + (1/k_7)(1 + k_8/k_9) + 1/k_9 + 1/k_{11}] \quad [8]$$

Note that c_{vf} , unlike c_f , does not consist of partition ratios. Rather k_5 , reduced by the factor $k_3/(k_3 + k_4)$, is compared to k_3 , and to each of the net rate constants after the chemical step. A low value of k_{11} , for example, can result in a large value of c_{vf} , and a greatly reduced expression of the isotope effect on V .

The slowest, least-conducting, and most-sensitive steps may be the same in an enzymatic reaction, but need not be, so one must define what one means when using the term 'rate limiting' for the maximum velocity.

Sugar Nucleotide Transporters

C B Hirschberg, Boston University School of Dental Medicine, Boston, MA, USA

© 2013 Elsevier Inc. All rights reserved.

Glossary

Glycosylation The covalent addition of sugars to each other or to proteins and lipids.

Golgi apparatus A membrane-enveloped organelle in the cytoplasm of all eukaryotes composed of several cisternae and vesicles; virtually all membrane-bound and secreted

proteins of eukaryotes traverse through this organelle en route to their final location within or outside the cell.

Nucleotide sugar Phosphodiester, usually between nucleoside 5'-diphosphates and carbon 1 of the sugar.

Phenotype The visual or physical characteristics of individual cells or a multicellular organism.

A Requirement for Sugar Nucleotide Transport into the Golgi Apparatus Lumen

Approximately half of all proteins in eukaryotic cells are secreted or membrane bound. These proteins are processed through the secretory pathway where 80% undergo posttranslational modifications such as glycosylation, sulfation, and phosphorylation in the lumen of the Golgi apparatus. Intact nucleotide sugars, nucleotide-sulfate, and adenosine 5' triphosphate (ATP), the substrates for these reactions, enter the lumen of the Golgi apparatus via specific transporter proteins (Figure 1). These are multi-transmembrane spanning proteins, which function as antiporters with the corresponding nucleoside monophosphates and thereby concentrate the nucleotide derivatives in the Golgi lumen relative to their concentration in the cytosol (Figure 1). Evidence for this mechanism has been obtained through biochemical studies with rat liver-derived Golgi vesicles as well as with different species of yeast. In the latter, gene disruption of a Golgi luminal guanosine 5' diphosphate (GDP)ase, which generates guanosine 5' monophosphate (GMP) (the antiporter molecule coupled to entry of GDP-mannose into the yeast Golgi lumen), results in severe undermannosylation of proteins and lipids *in vivo*, reduced transport of the GDP-mannose into Golgi vesicles *in vitro*, as well as in a failure to make hyphae in *Candida albicans*.

Mutants in Nucleotide Sugar Transport – Biochemical and Developmental Phenotypes Including Diseases

Mutant mammalian cells grown in tissue culture have been described as having 95% reduced transport of specific nucleotide sugars into their Golgi apparatus, while their proteins and lipids have a drastic reduction in the specific sugar transported by the corresponding nucleotide derivative transporters. Multicellular organisms such as *Caenorhabditis elegans*, *Drosophila melanogaster*, plants, and humans that have mutations in the above proteins also have distinct morphological phenotypes affecting development of limbs, wings, brain, etc. Studies of these mutants have shown that some of the transporters can translocate more than one nucleotide sugar, whereas other transporters retain high substrate specificity such as differentiating between sugar epimers.

Mutants in nucleotide sugar transport have also been described in *Leishmania donovani* and in yeasts such as *Saccharomyces cerevisiae*, *Kluyveromyces lactis*, and *C. albicans*.

Structure of Golgi Nucleotide Sugar Transporters

So far the primary amino acid sequence, together with the substrate specificity of approximately two dozen Golgi membrane nucleotide sugar transporters, has been determined. In most cases, this was done by correcting the phenotypes of mutant cells or mutant multicellular organisms with libraries containing wild-type DNA or cDNA from homologous or heterologous organisms. In most cases, after phenotypic correction, the specific DNA (or cDNA) was expressed in yeast or mammalian cells, Golgi vesicles were isolated, and transport of different nucleotide sugars assayed *in vitro*. Yeast is a particularly attractive system for heterologous expression of nucleotide sugar transporter genes, because it has few endogenous nucleotide sugar transport activities. This approach led to the identification of multisubstrate nucleotide sugar transporters from *C. elegans*. In some instances, a particular cDNA was also tested for its ability to correct the phenotype of mutant cells where the substrate specificity of the defective nucleotide sugar is known.

The fact that the above approaches for determining the substrate specificity of particular transporters have worked is based on the following points:

1. the transporters' DNA (or cDNA) can express the proteins in a heterologous system;
2. the targeting signals allowing the protein to localize to the Golgi apparatus are functional in different cell types; and
3. the targeted transporter is active once it reaches the Golgi apparatus of the recipient cell and can therefore affect phenotypic correction.

To date, the relationship of amino acid sequences and substrate specificities of nucleotide sugar transporters can be summarized as follows:

1. substrate specificities of nucleotides sugar transporters cannot be inferred even when amino acid sequences are ~50% identical;
2. only sequence identities of over 80% allow accurate predictions of substrate specificity; and

Figure 1 Golgi membrane nucleotide sugar, adenosine 3' phosphate 5' phosphosulfate (PAPS), and ATP transporters have been detected in mammals, yeast, protozoa, nematodes, insects, and plants. They are antiporters with the corresponding nucleoside monophosphate, except for PAPS, where the antiporter is not known, and for ATP, where it is either adenosine 5' monophosphate (AMP) or adenosine 5' diphosphate (ADP) or both.

- transporters from different organisms that have the same substrate specificity may have only 20% overall amino acid sequence identity.

Due to the above reasons the reader is cautioned that annotations about the identity (substrate specificity) of nucleotide sugar transporters in databases should be looked at very carefully!

Topography of Nucleotide Sugar Transporters in the Golgi Membrane

So far the only detailed topographic study of a nucleotide sugar transporter has been done with that for cytidine 5' monophosphate (CMP)-sialic acid in mammalian cells. Using a combination of tagged epitopes and immunocytochemistry, the transporter was found to have 10 transmembrane domains with both its amino and carboxy termini facing the cytosol. A study on the topography of the *K. lactis* uridine 5' diphosphate (UDP)-acetylglucosamine transporter using membrane accessibility of a peptide antibody and amino- and carboxy termini epitope tags also found that both termini face the cytosol and that this transporter has either six or eight transmembrane domains. It is important to stress that none of the existing algorithms in the literature are designed specifically to address the issue of protein topography in the Golgi apparatus membrane, which is somewhat thinner than the plasma membrane; most algorithms are designed for predicting topography in the plasma membrane.

Regulation of Macromolecular Glycosylation by Nucleotide Sugar Transporters

Studies with mutant mammalian cells in nucleotide sugar transporters grown in tissue culture as well as with fibroblasts

and lymphoblasts from patients with leukocyte adhesion deficiency (LAD) syndrome II showed that decreased concentrations of nucleotide sugar in the Golgi lumen result in selective hypoglycosylation of proteins rather than across the board reduction. Thus, mutant Madin-Darby canine kidney (MDCK) cells which have a 95% reduction in transport of UDP-galactose into their Golgi lumen, have a corresponding decrease in galactosylation of bulk glycoproteins, glycolipids, and keratan sulfate but not in heparan and chondroitin sulfates. LAD II patients appear to have normal O-fucosylation of Notch protein, whereas N-fucosylation of bulk proteins is drastically reduced. Although the detailed mechanism for these biochemical phenotypes is not understood, an attractive hypothesis is that when supply of nucleotide sugars is limited due to impairment in their transport, glycosylation reactions with lower K_m 's would proceed, whereas those with higher K_m 's would not.

Superoxide Dismutase

I Fridovich, Duke University Medical Center, Durham, NC, USA

© 2013 Elsevier Inc. All rights reserved.

Glossary

Apo enzyme Enzyme whose prosthetic group has been removed.

Cu, Zn SOD Superoxide dismutases with copper and zinc at the active site.

Fe SOD Superoxide dismutases with iron at the active site.

HO· The hydroxyl radical.

Homodimer Protein composed of two identical subunits.

Homotetramer Protein composed of four identical subunits.

Mn SOD Superoxide dismutases with manganese at an active site.

O₂⁻ The superoxide anion radical.

Introduction

Molecular oxygen (O₂), while essential for the life of aerobes, is potentially toxic. This toxicity is due to the propensity of O₂ for reduction by a univalent pathway. This facile univalent pathway of O₂ reduction generates intermediates that lie between one O₂ and its four electron reduction products – two molecules of water – and it is the reactivity of these intermediates that is responsible for the toxicity of O₂. In order of their production, these intermediates are the superoxide anion radical (O₂⁻), hydrogen peroxide (H₂O₂), and the hydroxyl radical (HO·). Superoxide dismutases (SODs) catalyze the conversion of O₂⁻ into H₂O₂ plus O₂, that is,

and, in so doing, provide an important defense. H₂O₂, in turn, is eliminated by the catalases and peroxidases. The concerted action of the SODs with the catalases and peroxidases prevents the formation of the very reactive HO·. This is the case because HO· production *in vivo* requires both O₂⁻ and H₂O₂. O₂⁻ oxidizes the [4Fe-4S] clusters of dehydratases, such as the aconitases, causing release of Fe (II); the freed Fe (II) then reduces H₂O₂ to OH⁻ plus HO· in a reaction known as ‘the Fenton reaction’.

The SOD Family of Enzymes

The first truly photosynthetic organisms were the cyanobacteria, and the oxygen they produced oxygenated a previously anaerobic biosphere. This imposed a common selection

pressure on what must have been a varied anaerobic biota. It is not surprising that several different SODs were then evolved to deal with the toxicity of the accumulating O₂ and that these persist to this day. Thus, there are SODs based on Cu (II) plus Zn (II), Mn (III), Fe (III), and Ni (II), all of which catalyze the dismutation of O₂⁻ into H₂O₂ + O₂.

All SODs work by a similar mechanism in which the metal at the active site is reduced by one O₂⁻ and then reoxidized by the next O₂⁻. The active site metal, thus, acts as a mediator passing an electron from one O₂⁻ to the next. In this way, the electrostatic repulsion, which would prevent close approach of one O₂⁻ to another, is bypassed by the SODs. All the SODs are very efficient catalysts and operate at close to the theoretical diffusion limit. Their rate constants for interaction with O₂⁻ are ~3 × 10⁹ M⁻¹ s⁻¹.

The Cu, Zn SODs

These SODs have been found in the cytosols of eukaryotic cells, the intermembrane space of mitochondria, the periplasm of Gram-negative bacteria, and in chloroplasts. The Cu (II) is linked to the Zn (II) at the active site by the imidazolate moiety of a histidine residue and this bridging imidazolate functions as a proton supply during the catalytic cycle. Thus, when the Cu (II) is reduced by O₂⁻, the Cu (I) releases the imidazolate that then protonates to imidazole. When the Cu (I) is reoxidized to Cu (II), the imidazole provides a proton to the nascent O₂⁻ converting it to HO₂⁻, as the bridging to the Zn (II) is reestablished. The HO₂⁻ that leaves the active site protonates in the water to H₂O₂. This mechanism can be depicted as follows:

Both of these half-reactions of the catalytic cycle proceed with a rate constant of $\sim 3 \times 10^9 \text{ M}^{-1} \text{ s}^{-1}$. The enzyme surface contains charged groups that provide an electrostatic funnel guiding the O_2^- toward the active site crevice. This electrostatic facilitation contributes to the efficiency of these enzymes.

The Cu, Zn SODs found in eukaryotic cytosols are homodimeric proteins with subunit weights of $\sim 16 \text{ kDa}$. The corresponding enzyme from the periplasm of *Escherichia coli* is monomeric. There is an extracellular Cu, Zn SOD found in higher animals. It is usually homotetrameric and glycosylated and has a subunit weight of $\sim 23 \text{ kDa}$.

The Mn SODs

These enzymes, whether from the matrix of mitochondria or bacteria, exhibit marked sequence similarity, reflecting a close evolutionary history and supporting an endosymbiotic origin for mitochondria. The bacterial enzyme is usually a homodimer, whereas the mitochondrial enzyme is a homotetramer. The subunit weight is $\sim 23 \text{ kDa}$. Some bacterial Mn SODs are tetrameric. This is the case in *Cryptococcus neoformans*. In *E. coli*, the biosynthesis of Mn SOD is under the control of the soxRS regulon, which coordinately upregulates the expression of a number of genes in response to O_2^- . The constitutively expressed SOX R protein is transcriptionally inactive in its reduced form. It can be oxidized by O_2^- and then activates the expression of the SOX S protein, which in turn activates all the genes in the regulon. Thus, Mn SOD is not measurable in extracts of anaerobically grown *E. coli*, but exposure of cultures to aerobic conditions elicits production of Mn SOD. Increasing production of O_2^- , by raising $p\text{O}_2$, or by adding compounds such as viologens, which can mediate enhanced production of O_2^- , increases the level of Mn SOD. It has been possible to force *E. coli* to produce Mn SOD to 7% of its soluble protein by aerobic exposure to the viologen paraquat.

The nectar of tobacco flowers has been found to contain a stable Mn-protein named nectarin that appears to be a Mn SOD.

The Fe SODs

These SODs, which are highly homologous to the Mn SODs, are found in bacteria and in plants. Although usually homodimeric, homotetrameric Fe SOD has been found in *Rhodococcus bronchialis* and *Mycobacterium tuberculosis*. The Fe SOD of *E. coli* is constitutive and thus is found even in anaerobically grown cells. It can thus be viewed as a standby defense against O_2^- , which is always maintained to protect in the event of a sudden exposure to O_2 .

It is possible to reversibly remove the metals from SODs. The apo enzymes so prepared are inactive but can be reactivated by restoring the active site metal. It is striking that, in spite of sequence and structural homologies, the Fe SOD is inactive when made to contain Mn in place of Fe and the Mn SOD is inactive when similarly reconstituted with the non-native metal Fe. There are, however, SODs that are active with either Mn or Fe at their active sites. These SODs, termed

'cambialistic SODs', are usually found in anaerobes such as *Propionibacterium shermanii* or *Streptococcus mutans*. These organisms produce the SOD with iron when grown anaerobically; however, when exposed to low levels of O_2 , produce the same SOD but with Mn. It is clear that even anaerobes have need of a defense against the O_2^- during transient exposure to O_2 . Ferrous salts are soluble and thus available anaerobically, but become insoluble when oxidized to the ferric state by O_2 . Manganous salts remain soluble under both conditions – hence, the wisdom of a cambialistic SOD for an anaerobe. An iron SOD has also been reported in the protozoan *Tetrahymena pyriformis*.

Deletions and Consequences

Escherichia coli

Mutants of *E. coli* lacking both the Mn SOD and the Fe SOD (SodA, SodB) have been prepared. Anaerobically, they grow as well as the parental strain. However, aerobically they grow slowly, exhibit a high rate of mutagenesis, and require branched-chain, sulfur-containing, and aromatic amino acids. The null mutants are also hypersensitive toward paraquat. All of these phenotypic deficits disappear when a functional gene encoding any active SOD is inserted. The slow growth of the null mutant can be understood in terms of the energy devoted to repairing or replacing oxidatively damaged molecules and to the inactivation of such O_2^- -sensitive enzymes as aconitase. The high rate of O_2 -dependent mutagenesis reflects oxidative DNA damage, and repair, which is error prone. The nutritional auxotrophies exhibited by the null mutant have several explanations. The need for branched amino acids arises because the penultimate step in the biosynthesis of these amino acids is catalyzed by a dihydroxy acid dehydratase that contains a [4Fe-4S] cluster that is rapidly oxidized, and inactivated, by O_2^- . The need for sulfur-containing amino acids evidently reflects leakiness of the cell envelope toward sulfite, which is an intermediate on the pathway from sulfate to cysteine. Finally, the aromatic amino acid auxotrophy reflects the inability to make erythrose-4-phosphate, which is one of the starting materials on the pathway leading to these amino acids. Erythrose-4-phosphate, in turn, depends on the sequential actions of transketolase and transaldolase, and the transketolase intermediate 1,2-dihydroxyethylthiamine pyrophosphate is rapidly oxidized by O_2^- . The varied explanations for these phenotypic deficits reflect the variety of damage that can be caused by O_2^- and the multiple targets that are protected by the SODs.

Yeast

Mutants of the yeast *Saccharomyces cerevisia* lacking either the cytosolic Cu, Zn SOD, or the mitochondrial Mn SOD have been prepared. Their phenotypic deficits, which are all oxygen dependent, include slow growth, hypersensitivity toward paraquat or quinones, vacuolar fragmentation, sensitivity toward oxygen, and, in the case of the Cu, Zn SOD-null, lysine auxotrophy. All of these problems can be explained on the basis of O_2^- damage, as was the case for the *E. coli* SOD-null mutants.

Mice

Murine mutants lacking Mn SOD are severely affected and the homozygotes that survive to term are low birth weight and only survive for 4–14 days. Additional phenotypic deficits that have been attributed to subnormal levels of the MnSOD, such as that seen in heterozygotes, include anemia, neuronal degeneration, cardiomyopathy, increased oxidative damage to mitochondrial DNA, diminished levels of glutathione and aconitase, and increased susceptibility to reperfusion injury. Their problems can be seen as a deficit of mitochondrial functions and that in turn can be explained on the basis of damage to mitochondrial components by O_2^- .

In contrast to the embryonic and neonatal fatality imposed by Mn SOD deletion, the homozygous Cu, Zn SOD-null mice were apparently normal, while young, under laboratory conditions. They are, however, reported to be relatively intolerant of neuronal injury and prone to develop hepatoma at >9 months of age. Other debilities seen as these mice age include shortened life span, hearing loss, motor neuron axonopathy, and retinal degeneration. It seems likely that there is some redundancy in scavenging O_2^- in the cytosol, so that the lack of Cu, Zn SOD may be partially compensated by upregulation of another O_2^- scavenger, perhaps a superoxide reductase, similar to that found in anaerobes. The sum of the problems exposed by the loss of SOD activities, and that can be corrected by restoration of SODs, reflects the multiple damages that can be inflicted by O_2^- .

SOD and Amyotrophic Lateral Sclerosis

Amyotrophic lateral sclerosis (ALS) or Lou Gherig's disease is a late-onset, progressive, and fatal paralytic disease due to death of motor neurons. There are sporadic and familial types of ALS and these are not distinguishable on the basis of clinical symptoms. Approximately 20% of the familial cases of ALS have been associated with point mutations causing single amino acid replacements in Cu, Zn SOD. Transgenic mice expressing the wild-type human Cu, Zn SOD are normal, but those expressing one of the ALS-associated mutant Cu, Zn SODs develop progressive paralysis at ~3 months of age. Thus, the mutations in the abundant SOD cause the death of motor neurons because of some gain of function, rather than because of a loss of SOD activity. This is certainly the case because most of the familial ALS-associated mutant SODs retain full SOD

activity; the transgenic mice retain the active murine Cu, Zn SOD; the disease is genetically dominant, that is, heterozygotes develop the disease; and, finally, Cu, Zn SOD knockout mice do not develop ALS. It appears that the mutant SODs all exhibit decreased stability, particularly while in their metal-free apo forms, and are prone to aggregation. The accumulation of protein aggregates may be particularly damaging to motor neurons because such aggregates interfere with transport within their very long axons. These transgenic mice provide a useful model of the human disease and are being used to explore both the toxic gain of function of the mutant Cu, Zn SOD and treatment modalities.

Mimics

O_2^- has been found to play causative roles in numerous inflammatory diseases and reperfusion injuries. For this reason, non-enzymic catalysts of the dismutation of O_2^- are being explored as pharmaceutical agents and appear to have promise.

This article is reproduced from the previous edition, volume 4, pp. 147–151, © 2004, Elsevier Inc.

Glossary

Downstream The direction in which an RNA polymerase moves along the DNA during transcription.

Primer A DNA or RNA molecule, typically short, that is extended by a DNA polymerase during DNA replication.

Promoter A DNA from which an RNA polymerase initiates transcription.

Template strand When a nucleic acid directs the synthesis of DNA or RNA, the template strand selects – by Watson–Crick base pairing – the nucleotides incorporated into the newly synthesized molecule.

Transcription The synthesis of RNA using a DNA template.

DNA-Directed RNA Polymerases

The enzymes which synthesize nucleic acids – the polymerases – are functionally defined on the basis of whether they use DNA or RNA as a template, and whether they synthesize RNA or DNA. The DNA-directed RNA polymerases comprise two large families. One includes the large multi-subunit cellular RNA polymerases which synthesize the messenger and ribosomal RNAs of all cells. The other family includes the mitochondrial and chloroplast RNA polymerases, and the RNA polymerases encoded by a variety of bacteriophage. These are simpler, typically single-subunit, enzymes. The best-characterized representative of this family is the RNA polymerase of the T7 bacteriophage.

T7 RNA Polymerase

Structure

Three-dimensional structures of T7 RNA polymerase in isolation and in complexes with nucleic acids and nucleotide triphosphate (NTP) substrates have been determined by X-ray crystallography. The polymerase is comprised of an N-terminal domain (amino acids 1–312), and a C-terminal domain (amino acids 313–883). The C-terminal domain is further subdivided into thumb (amino acids 330–410), palm (amino acids 411–448, 532–540, 788–838), and fingers (amino acids 541–737, 771–778) subdomains, which are so designated because together they form a structure similar in shape to a cupped right hand. Nucleic acids bind within the large cleft in this structure (Figure 1).

Structure–Function Relationships

The C-terminal domain contains the active site where RNA synthesis occurs. Phosphodiester bond formation is catalyzed by two Mg^{2+} ions complexed by two aspartates (D537, D812) of the palm subdomain (Figure 2). The thumb subdomain makes interactions with the RNA that stabilize the transcription complex, while the fingers subdomain binds the template strand and contains residues which bind the NTP and which discriminate ribo-NTPs from deoxyribo-NTPs. Residues 739–770 of the C-terminal domain form a promoter recognition loop which makes sequence-specific interactions with the –7 to –11 base pairs (bp) of the promoter. The C-terminal domain also contains the binding site for the regulatory factor T7 lysozyme, and residues 839–883 form a C-terminal extension which functions in the allosteric mechanism by which T7 lysozyme regulates transcriptional activity. The N-terminal domain is involved in nascent RNA binding, in sequence-specific binding to the promoter, and in separating (opening) the two strands of the promoter during initiation so as to expose one strand for templating RNA synthesis. Residues 93–101 of the N-terminal domain are rich in positively charged amino acids and make specific interactions with the AT-rich –13 to –17 bp of the T7 promoter, whereas residues 232–242 form a β -hairpin which inserts between the two DNA strands to open the promoter.

Similarities to Other Polymerases

T7 RNA polymerase shares extensive sequence similarity with mitochondrial and chloroplast RNA polymerases and with

Figure 1 Structural organization of T7 RNA polymerase and its conformational changes. (a) Ribbons model of the polymerase domain of DNA pol 1 (pdb 1KLN) with its thumb subdomain (amino acids 546–656) in green, its palm subdomain (amino acids 657–707, 854–928) in cyan, and its fingers subdomain (amino acids 708–853) in blue. The active site center is indicated by a space-filling representation of the aspartate 882 side chain (in dark cyan). (b) Ribbons model of a T7 RNA polymerase initial transcription complex with a 3-nt RNA (pdb 1QLN). The portion of T7 RNA polymerase homologous to the polymerase domain of DNA pol I (amino acids 330–448, 532–737, 771–838) is in green. This T7 RNA polymerase domain is accessorized with an N-terminal domain (amino acids 1–329; orange), a domain of unknown function (amino acids 449–531; yellow), the promoter recognition loop (amino acids 738–770; magenta), and a C-terminal extension (amino acids 839–883; gray). The center of the active site is indicated by a space-filling representation of side chain of aspartate 812 in dark cyan. The template and nontemplate strands of the promoter DNA are blue and cyan, respectively, and the RNA is red. (c) Ribbons model of a T7 RNA polymerase initial transcription complex with an 8-nt RNA (pdb 3E3J). Relative to the structure in (b), the N-terminal domain and promoter recognition loop have rotated away from the rest of the polymerase to make room for the growing RNA:DNA hybrid while maintaining their interaction with the upstream, base-paired part of the promoter. (d) Ribbons model of a T7 RNA polymerase elongation complex with a 10-nt RNA (pdb 1MSW). Relative to the structure in (c), the N-terminal domain has taken on a completely new fold and the upstream DNA has moved to a new location on the polymerase surface. (e) Model of a T7 RNA elongation complex with NTP (purple and in space-filling representation) bound (pdb 1S76). Relative to the structure in (d), the fingers subdomain (green) has rotated toward the NTP and the fingers flap (amino acids 590–612; colored light gray in (d)) has moved away from the downstream DNA and assumed a disordered conformation. (f) Model of the elongation complex paused at the T7 concatemer junction (CJ). Relative to the structure in (e), the upstream DNA has swung from one site on the polymerase to establish an interaction with a different site. (g) Model of T7RNA polymerase bound to the regulatory inhibitor, T7 lysozyme (in blue). Relative to the other T7 structures shown, the T7 lysozyme-bound polymerase has its C-terminus (indicated by an asterisk) pulled out of the active site and exposed to solvent.

other bacteriophage-encoded RNA polymerases. T7 RNA polymerase is also structurally similar to the DNA-directed DNA polymerases of the pol I/pol α family, to the RNA-directed DNA polymerases (reverse transcriptases), and to the RNA-directed RNA polymerases. However, unlike the extensive sequence similarities between the mitochondrial, chloroplast, and phage RNA polymerases, the identifiable sequence similarities between T7 RNA polymerase and the DNA polymerases, reverse transcriptases, and RNA-directed RNA polymerases are limited to a few well-conserved amino acids in a small number of sequence motifs. The structural similarity suggested by this limited sequence similarity is confirmed by comparison of the three-dimensional structures of these enzymes (Figure 1).

This comparison also reveals that functions specific to particular classes of polymerase are incorporated by accretion of structurally dissimilar domains or modules onto a structurally conserved core. For example, DNA polymerase I and T7 RNA polymerase both exhibit structurally similar thumb, palm, and fingers subdomains which together form a polymerase domain with the core function of processive template-directed nucleic acid synthesis. In T7 RNA polymerase, this conserved core is accessorized with modules that include the N-terminal domain, which is involved in the RNA polymerase-specific functions of promoter recognition and opening, RNA binding and displacement, and transcription bubble resolution and transcription termination. They also include the promoter

recognition loop, which is responsible for sequence-specific binding of the T7 promoter, and the C-terminal extension, which is involved in regulation by T7 lysozyme. None of these modules have structural or functional counterparts in DNAP I which, instead, is accessorized with unrelated domains that carry out the exonucleolytic and proofreading activities required for an enzyme involved in DNA repair and highly accurate genome replication (Figure 3).

Figure 2 Bond formation in nucleic acid synthesis. The 3'-OH of the nucleotide at the end of the DNA primer or RNA attacks the α -phosphate of the NTP. A new bond is formed, and the β - and γ -phosphates of the NTP are lost as pyrophosphate. The reaction is catalyzed by two metal ions which stabilize both the negative charge on the 3'-OH to enhance its nucleophilicity and the negatively charged pentacovalent α -phosphate intermediate which forms during the transition state. The two metal ions are bound by the side chains of two aspartic acids (D537 and D812 in T7 RNA polymerase) which are found in the active sites of all homologous polymerases.

T7 RNA Polymerase: Transcription Reaction and Conformational Change

Promoter Structure, Recognition, and Opening

The T7 promoter is 23 bp in length and has a tri-partite structure (Figure 4). The -17 to -6 sequence is important for specific binding of the polymerase via interactions between residues 746, 748, 756, and 758 and the -7 to -11 bp, and between residues 93–101 and the -13 to -17 bp (bases are numbered relative to the transcription start site at $+1$). The -17 to -6 bp remain duplex during transcription initiation. The -4 to -1 TATA sequence facilitates promoter opening, which begins at the -4 bp and extends downstream, driven by imposition of a sharp ($\sim 50^\circ$) bend in the promoter when polymerase binds, and by insertion of β -hairpin (residues 231–242) between the DNA strands. The $+1$ to $+6$ initially transcribed sequence enhances the efficiency of the initial transcription reaction. Seven class III T7 promoters occur in the T7 genome and exhibit a perfect match to the sequence shown in Figure 4. There are also 16 less active class II T7 promoters in the T7 genome which typically exhibit a small number of base-pair differences from the class III consensus.

Initial Transcription

Once bound, the polymerase rapidly opens the promoter but the promoter closes again even more quickly unless initiating NTPs bind to stabilize the open complex. Binding of initiating NTPs is followed by their catalytic joining to form a dinucleotide RNA which can then be further extended. When this nascent RNA is small (<12 nucleotides (nt)), the transcription complex is unstable and short RNAs are frequently released from the complex. Once an RNA is released, the polymerase reinitiates, usually without releasing the promoter. For this reason this initial phase of transcription, which is also characteristic of multi-subunit cellular RNAPs, is also referred to as abortive transcription. Throughout this initial phase of transcription, the polymerase retains the specific promoter interactions made with the -17 to -6 bp in the initial binding step. Transcription to $+8$ is achieved by threading the template strand through the active site and by compacting (scrunching) it within the template-binding cleft, as well as by conformational changes that rotate the N-terminal domain away from the C-terminal domain so as

to expand the size of the template-binding cleft to accommodate the growing RNA:DNA hybrid (**Figure 1(c)**).

Promoter Release and Elongation

When the RNA reaches 9 nt in length, the polymerase can release the promoter in a step that involves a large conformational change in which the promoter recognition loop and N-terminal domain move apart to break up the promoter-binding surface created jointly by these two elements (**Figure 1(d)**). This conformational change also refolds the N-terminal domain, leading to the formation of a tunnel through which the emerging RNA passes. The result of all these changes is a stable, processive elongation complex with a ~ 10 base transcription bubble and an ~ 8 -bp RNA–DNA hybrid, which can synthesize transcripts thousands of nucleotide in length at rates of $200\text{--}300\text{ nt s}^{-1}$. During elongation, movement of the complex occurs by a thermal (Brownian) ratchet mechanism, in which the elongation complex slides rapidly and reversibly around the 3'-end of the RNA until the binding of a complementary NTP in the active site induces closing of the fingers subdomain (**Figure 1(e)**) and locks the complex down long enough for an NMP to be added to the growing

chain. Upon release of the pyrophosphate, the fingers subdomain opens and the cycle of reversible sliding of the elongation complex around the 3'-end of the RNA begins again.

Pausing and Termination

Certain DNA sequences can act as pause or terminator sites and interrupt the progress of the elongation complex. Terminators designated 'class I' contain a sequence which can form a G:C-rich hairpin when transcribed into RNA with a U-rich element immediately downstream (**Figure 5**). Formation of a hairpin in the RNA is expected to disrupt interactions made between the polymerase and single-stranded RNA 8–14 nt away from the RNA 3'-end and to disrupt part of the RNA:DNA hybrid. Disruption of these interactions weakens the association of the RNA with the elongation complex, and the U-rich nature of the remaining RNA:DNA base pairs further weakens the RNA's association with the complex, leading to release of the RNA and transcription termination. A class I terminator appears between genes 10 and 11 in the T7 genome, where it is important for attenuating transcription of downstream genes.

A sequence, AUCUGUU, found uniquely at the junction between the concatemerized T7 genomes generated during T7 DNA replication has also been found to cause the elongation complex to pause and to be an effective terminator when coupled with a downstream U-rich element. This sequence has therefore been designated the concatemer junction (CJ) element or class II terminator. Unlike class I terminators, the CJ element exhibits no obvious potential for forming secondary structure in the RNA, though it has been suggested that the CJ RNA can form a divalent metal-binding site that could partially disrupt CJ RNA base pairing with the template DNA. This could account for the observation that the upstream half of the transcription bubble re-anneals at the CJ element leading, in turn, to a dramatic change in the DNA architecture of the elongation complex, because this re-annealing disrupts a bend in the DNA located at the upstream edge of the transcription bubble (**Figure 1(f)**). This large change in the structure of the elongation complex may mediate not only its pausing, but also be the signal that recruits the T7 DNA packaging machinery to the CJ element, as pausing of the T7 RNA polymerase elongation complex at the CJ is required for the cutting of the genome concatemers into individual genome lengths and packaging into viral capsids. Sequences identical to the T7 CJ occur in related phage at similar positions in their genomes and also cause pausing by the polymerases encoded by those phage, implying that this is a conserved mechanism among phage that encode a T7 RNA polymerase homolog.

Regulation

During the T7 life cycle, the transcriptional activity of T7 RNA polymerase is regulated by T7 lysozyme, which binds to the polymerase and inhibits transcription initiation. Inhibition is allosteric: lysozyme binding changes the conformation of the C-terminal extension (amino acids 839–883) of the polymerase (**Figure 1(g)**). This conformational change weakens the affinity of the polymerase for NTPs and short RNAs. This, in turn, reduces the rate of transcription initiation at limiting NTP

concentrations, and decreases the efficiency of progression through initial transcription by increasing the frequency with which short RNAs are released from the complex during abortive transcription. These inhibitory effects are greater for class II promoters, which, relative to class III promoters, display intrinsically higher rates of RNA release during initial transcription and require higher NTP concentrations to achieve high rates of initiation. Class III promoters drive transcription of genes which encode proteins, such as phage coat proteins, that are required late in infection, whereas class II promoters drive transcription of genes which encode proteins required during the early and middle stages of phage infection, such as proteins involved in replication of the phage DNA. Thus, in a T7-infected *Escherichia coli*, the accumulation of T7 lysozyme late in the phage life cycle leads to a disproportionate decrease in transcription from class II promoters and to an increase in the production of the late phage proteins required for assembly of the mature phage particles. As T7 lysozyme is itself encoded by a gene transcribed from a class II promoter, an autoinhibitory feedback loop is created which ensures that repression by T7 lysozyme is kept within an appropriate range.

Priming DNA Replication

In addition to its primary function of transcribing the T7 phage genes, T7 RNA polymerase also primes rightward replication of T7 DNA. Priming occurs within an A-T-rich region immediately downstream of two T7 promoters (dubbed 1.1a and 1.1b) which are located at the T7 origin of replication. The mechanism by which the RNA primer initiated at these promoters is transferred from T7 RNA polymerase to T7 DNA polymerase is not understood.

Conformational Changes during the Transcription Reaction

The number of functionally distinct conformational isomers revealed for T7 RNA polymerase is probably greater than has been seen with any other well-characterized macromolecule. Relative to the crystal structure of the isolated polymerase, the early initiation complex (RNA < 5 nt in length; **Figure 1(b)**) exhibits significant ordering of loops and elements involved in nucleic acid interactions. The early initiation complex then changes significantly as the RNA is extended beyond 5 bases in length as the N-terminal domain rotates away from the C-terminal domain to accommodate the growing RNA:DNA hybrid and form the late initiation complex (**Figure 1(c)**). The late initiation complex is even more extensively remodeled by refolding of the N-terminal domain to form the elongation complex (**Figure 1(d)**). During elongation, every cycle of nucleotide addition is characterized by closing of the fingers subdomain and an order to disorder transition in the fingers flap (amino acids 590–612) coincident with NTP binding (**Figure 1(e)**). Regulatory inhibition by T7 lysozyme involves an allosteric change in which lysozyme binding causes the well-conserved, hydrophobic and functionally critical C-terminus of the polymerase to be extruded from the active site (**Figure 1(g)**). Finally, pausing at the CJ or class II terminator element involves partial transcription bubble collapse and a drastic change in elongation complex architecture (**Figure 1(h)**). This extensive conformational plasticity could be a consequence of selective

pressure on the T7 phage to maintain a small genome size to allow for rapid replication, so that maximum functionality must be packed into every protein. Whether this adaptive explanation is correct or not, these observations reveal the extraordinary degree of conformational variation that can be accessed by a macromolecule in executing its function.

T7 RNA Polymerase: Applications

The stringent promoter specificity and robust transcriptional activity of T7 RNA polymerase have been taken advantage of to overexpress proteins *in vivo* and to synthesize RNAs *in vitro*. In the most widely used embodiment of the former application, the gene encoding T7 RNA polymerase is placed under the control of an inducible promoter and is then stably integrated into the genome of an *E. coli* cell. A plasmid carrying the gene of interest under the control of a T7 promoter is then introduced into *E. coli*. When the gene encoding the T7 RNA polymerase is induced, the expressed T7 RNA polymerase transcribes the gene of interest at a high level, resulting in overproduction of the desired gene product. Similar approaches are used to overexpress proteins in eukaryotic cells. Synthesis of specific RNAs *in vitro* is done by using purified T7 RNA polymerase and templates in which a sequence of interest is placed downstream of a T7 promoter. Mutant T7 RNA polymerases and special reaction conditions have been developed that allow utilization of noncanonical NTP substrates containing, for example, a fluorine rather than a hydroxyl group at the ribose 2'-position. Such modifications can endow the RNAs with desired properties, such as resistance to RNA degrading enzymes in therapeutic applications. Such RNAs, synthesized with natural or modified NTPs, are commonly used for a wide variety of research purposes and as diagnostic and therapeutic reagents.

Glossary

Carboxyl tail The hydrophilic portion of a G-protein-coupled receptor (GPCR) that follows the final transmembrane-spanning domain (TM7), extending from the cytosolic face of the plasma membrane and terminating in the cytosolic compartment of the cell.

G-protein-coupled receptor (GPCR) Integral plasma membrane proteins having seven hydrophobic, transmembrane-spanning domains (designated TM1 through 7). GPCRs pass signals across the plasma membrane by transducing stimuli from extracellular signaling molecules to intracellular G proteins. G proteins, in turn, activate intracellular signaling cascades.

Phospholipase An enzyme that can hydrolyze the phosphodiester bond in phospholipids and produce soluble inositol lipids and membrane-bound diacylglycerol; type C phospholipases specifically use phosphoinositides as substrates.

Preprotachykinins The genes containing all the DNA sequence information needed to synthesize tachykinins. The actual production of tachykinins requires alternative splicing of messenger RNA (mRNA) transcripts derived from preprotachykinin, and posttranslational modification of peptides generated from the mRNA transcripts.

Tachykinin A 10–11-amino-acid peptide, having the amino acid sequence F-X-G-L-M-NH₂ at the C-terminal end, where X is a hydrophobic amino acid residue. Tachykinins are released from neurons and act as neurotransmitters.

Tachykinins

Tachykinins are peptides of 10–11 amino acids having the motif F-X-G-L-M-NH₂ at the C terminus; the –NH₂ group indicates that the C-terminal amino acid is amidated, a post-translational modification necessary for biological activity.

There are currently four known mammalian tachykinins: substance P (SP), neurokinin A (NKA), neurokinin B (NKB), and hemokinin 1 (HK-1). As illustrated in [Figure 1](#), these tachykinins are generated from three genes: preprotachykinin-A (PPT-A), preprotachykinin-B (PPT-B), and preprotachykinin-C (PPT-C). Alternative splicing of the PPT-A messenger RNA (mRNA) transcripts yields four products: α -PPT-A, β -PPT-A, γ -PPT-A, and δ -PPT-A. α -PPT-A and δ -PPT-A encode only SP, while β -PPT-A and γ -PPT-A encode both SP and NKA. PPT-B yields only one product, NKB, and PPT-C encodes HK-1. The products of PPT-A transcripts (SP and NKA) are found in the central nervous system (CNS) and across a range of peripheral tissues, while a product of PPT-B (NKB) is found only in the CNS. PPT-C is widely distributed in many peripheral organ systems, but is not detected in the CNS.

The actions of mammalian tachykinins are mediated by three receptors: neurokinin-1 receptor (NK1R), neurokinin-2 (NK2) receptor, and neurokinin-3 (NK3) receptor. These receptors have the following binding preferences: NK1R binds in the order SP>NKA>NKB; NK2 binds in the order NKA>NKB>SP; and NK3 binds in the order NKB>NKA>SP. Although SP, NKA, and NKB bind the tachykinin receptors with different affinities, they are all full agonists at all three receptors.

Mammalian Tachykinin Function

Substance P

SP is present in the outer laminae of the dorsal horn of spinal cord and in many areas of the brain, which is consistent with

SP acting as a neurotransmitter. The hypothesis that SP has a role in pain transmission stems from its presence in primary afferent nerve fibers of the spinal cord, such as C-fibers of laminae I and II of the dorsal horn. Efforts aimed at developing NK1R antagonists to treat pain have met with limited success, causing some doubt about the involvement of SP in pain transmission. However, recent experiments performed in genetically engineered mice, which lack expression of PPT-A, have given new support for the role of SP in pain. While mice lacking PPT-A display normal responses to a variety of painful stimuli, their responses become blunted as the stimulus increases in intensity. However, above a certain pain threshold, mice lacking PPT-A seem to display responses that are similar to control mice. These results suggest that SP is indeed a pain neurotransmitter, and it functions within a discrete window of pain intensities. Other recent studies in mice lacking NK1R also support the conclusion that SP plays a role in pain transmission.

SP also influences blood pressure. Intravenous injection of tachykinins in dogs and rabbits produces a strong hypotensive effect on mean arterial blood pressure, with SP showing much higher potency than NKA, NKB, or nonmammalian tachykinins. In human volunteers, intravenous SP causes a drop in diastolic, but not systolic, blood pressure, whereas NKA has no effect on either. Interestingly, the hypotensive effect is not diminished by autonomic blocking agents, such as atropine, atenolol, or prazosin. This observation suggests that SP acts directly on vascular smooth muscle.

Substance P/Neurokinin A

The PPT-A mRNA transcripts that produce NKA (β - and γ -PPT-A) also produce SP ([Figure 1](#)); thus, SP and NKA are cosynthesized and coreleased from neurons. This suggests that NKA does not act alone; however, NKA can act as the primary signaling peptide in situations where the ratio of NKA to SP

Human tachykinins

favors NKA, and where NK2 (the preferred receptor for NKA) is the predominant receptor in the target tissue. NKA is recognized as a very potent bronchoconstrictor, more potent than SP or NKB. Blockade of nerve-evoked bronchoconstriction by an antiserum having high affinity for NKA indicates that NKA has a more important role than SP in bronchoconstriction. Furthermore, experiments using NK2-selective antagonists indicate a predominance of NK2 over NK1R in the mediation of noncholinergic bronchoconstriction responses. NKA is also more potent than SP in decreasing tracheal vascular resistance. Recent data indicate that NKA, like SP, binds to NK1R with high affinity; thus, the effects of NKA may potentially be mediated by either NK1 or NK2 receptor. In the CNS, which does not contain NK2 receptors, NKA produces biological effects similar to SP by interacting with NK1R.

Neurokinin B

Although SP and NKA frequently have overlapping tissue distribution, the distribution of NKB is distinct from that of SP and NKA. For example, NKB is present in spinal cord laminae III, while SP and NKA are abundant in laminae I and II and absent in laminae III. NKB is most abundant in the hypothalamus and in the intestines. The physiological effects of NKB include contraction of rat portal vein and inhibition of gastric acid secretion. Interestingly, NKB potently decreases alcohol intake by a strain of alcohol-preferring rats. Also of potential clinical importance, NKB dilates the vasculature in human placenta and is thought to have an important role in the development of preeclampsia.

Hemokinin 1

Discovered in 2000, the tachykinin HK-1 is unique in that it is not of neuronal origin. HK-1 was first cloned from mouse B-lymphocytes; subsequent cloning of human HK-1 showed that it differs from mouse HK-1 in 5 out of 11 amino acid residues.

Expression of human HK-1 has since been demonstrated in heart, skeletal muscle, thyroid, and skin. Weaker expression is detected in liver, lung, stomach, testes, placenta, and prostate. Receptor-binding assays in cultured cells and tissues show that HK-1 has a strong binding preference for NK1R over NK2 or NK3 receptors, and it is considered a full agonist of NK1R.

HK-1 is similar to SP in many physiological effects, often with a potency that is very close to that of SP. Intravenous injection of HK-1 or SP into guinea pigs produces a dose-dependent hypotensive effect, with HK-1 and SP decreasing diastolic blood pressure at similar potencies of 0.2 nmol kg⁻¹ and 0.1 nmol kg⁻¹, respectively. HK-1 and SP also induce salivary secretion in rats at essentially equal potencies. Studies are underway in several laboratories to develop a more complete understanding of the function of HK-1.

Neurokinin-1 Receptor

NK1R and the other tachykinin receptors belong to the G-protein-coupled receptor (GPCR) superfamily of receptors, which are characterized by the presence of seven hydrophobic transmembrane domains, designated TM1 through 7 (Figure 2). Cloning of human NK1R from glioblastoma cells yields two forms of the receptor. One clone, with a stop codon after amino acid 407, encodes a full-length receptor and the other, with a stop codon after amino acid 311 (Δ 311, Figure 2), encodes a truncated form of the receptor; the truncated form has also been cloned from guinea pig nervous system.

Full-Length NK1R

NK1R has three extracellular (EC) and three intracellular (IC) hydrophilic loops, a fourth IC loop formed by the palmitoylation of a cysteine residue, and in the case of the full-length receptor, a carboxyl tail. The deduced amino acid sequences of full-length rat and human NK1R reveal that these receptors are

Figure 2 Two-dimensional representation of the human NK1R. The amino acid sequence of human NK1R is shown. Seven putative transmembrane regions are labeled TM1–7, three extracellular loops are labeled EC1 through 3, and four intracellular loops are labeled IC1 through 4. Shaded circles show where amino acid residues in rat NK1R differ from human NK1R. Arrows indicate the termination site of the short form of NK1R at Arg311, and truncation site of the mutant rat NK1R at Phe325.

407 amino acids long and share 95% amino acid identity; there are only 22 amino acids that differ between rat and human NK1R (see shaded circles in [Figure 2](#)).

Although rat and human NK1R are very similar at the amino acid level, they interact differently with SP and several nonpeptide antagonists of NK1R. For example, SP binds to rat NK1R with a K_d of 3 nM, whereas it binds to human NK1R with a higher affinity characterized by a K_d of 0.7 nM. The difference between rat and human NK1R pharmacology becomes even more striking for some of the nonpeptide antagonists. CP-96345, the first nonpeptide antagonist of NK1R to be synthesized, has 100-fold higher affinity for human NK1R than for rat NK1R, and the nonpeptide antagonist RP67580 has higher affinity for rat NK1R than for human NK1R.

As rat and human NK1R differ in only a few amino acid residues in the TM domains (a region believed to be involved in ligand binding), several groups have identified the amino acids responsible for differences in their pharmacology. These groups found that residue 290 in TM7 and the residues located on the second EC loop contribute to the selectivity of CP-96345 for human NK1R. Histidine 197 in TM5 is involved in the binding of CP-96345, whereas histidine 265 in TM6 is involved

in RP67580 binding. These mutagenesis studies not only identify the residues involved in conferring species-dependent pharmacology to NK1R, but also show that ligand binding to the receptor involves the TM domain as well as amino terminus and EC loops.

NK1R activation in most cells stimulates phospholipase C, which hydrolyzes membrane phosphoinositides into two second messengers: inositol triphosphate (IP_3) and diacylglycerol. These molecules stimulate intracellular calcium release and protein kinase C (PKC) activation, respectively. Studies using U373 human glioblastoma cells, in which NK1R occurs naturally, implicate several key molecules in NK1R signaling, including mitogen-activated protein (MAP) kinases ERK1/2, MAP kinase p38, nuclear transcription factor kappa B ($NF-\kappa B$), and epidermal growth factor receptor (EGFR). Of these molecules, ERK1/2 mediates NK1R-stimulated proliferation of U373 MG cells through nonreceptor tyrosine kinase Src. A recent study found that stimulation of NK1R leads to increased phosphorylation and activation of Akt, or protein kinase B, through total involvement of Src and PI-3-kinase, and partial involvement of EGFR. In addition, blockade of NK1R resulted in apoptosis of glioblastoma cells. These findings emphasize the relevance of the

NK1R signaling pathways to understanding the mechanism of glioblastoma growth.

Truncated NK1R

Functional studies in which the truncated (NK1R Δ 311) and full-length forms of NK1R were expressed in *Xenopus* oocytes revealed that the truncated receptor is 100-fold less active than full-length NK1R. Ligand binding analyses of the full-length and truncated forms of NK1R expressed in COS cells reveal that the truncated form binds SP with much lower affinity. More recent studies on full-length and truncated NK1R expressed in HEK 293 cells revealed several differences in signaling through these receptors, including differences in time course of ERK1/2 activation. Interestingly, truncated NK1R, but not the full-length NK1R, expressed in normal breast cells resulted in a transformed phenotype. Furthermore, the expression of truncated NK1R, but not the full-length, was controlled by NF- κ B.

Role of the Carboxyl Tail in NK1R Function

Potentially, the full-length and truncated NK1 receptors could mediate SP signaling differently in different tissues due to the presence or absence of the carboxyl tail; thus, it is important to understand the function of the carboxyl tail in NK1R biology.

One function of NK1R in which the carboxyl tail plays an important role is receptor desensitization. Like many other GPCRs, NK1R undergoes agonist-induced desensitization, a phenomenon in which the responsiveness of the receptor diminishes in spite of the continued presence of the stimulus. Studies performed by Dr. Lefkowitz at Duke University Medical Center and by several other investigators have shown that agonist-specific or homologous desensitization of GPCRs proceeds through two cytosolic proteins, G protein-coupled receptor kinases (GRKs) and β -arrestins. GRKs phosphorylate agonist-occupied receptor at serine and threonine residues on the carboxyl tail and IC loops, and this phosphorylation primes the receptor to bind β -arrestins. The binding of β -arrestin to the intracellular face of the receptor disrupts interactions between the receptor and G protein, resulting in a loss of signaling (Figure 3). β -Arrestin binding also directs receptor internalization through clathrin-coated pits.

As the carboxyl tail plays a key role in GPCR desensitization, its absence would be expected to impair the ability of truncated NK1R to desensitize. However, studies examining the role of the C terminus in rat NK1R desensitization have yielded varying results. It has been reported that a C-terminally truncated mutant of rat NK1R Δ 325 does not desensitize fully, while other studies have reported no loss of desensitization in the same truncation mutant. We had also examined the effect of C-terminal truncation on the desensitization of human

Figure 3 Model of homologous GPCR desensitization. (a) In the resting state, receptor, G protein and effector are inactive. (b) Occupancy of the receptor by agonist enables it to catalyze G-protein activation, leading to activation of the effector by G protein. Receptor occupancy also makes it a target for phosphorylation by GRK. (c) Phosphorylation diminishes the ability of the receptor to activate G protein; the effector then reverts to the inactive state. Phosphorylation also facilitates the association of β -arrestin with the receptor. (d) Association of β -arrestin with phosphorylated receptor prevents any further G-protein activations even though agonist is present.

NK1R by preparing a truncated mutant that ended at amino acid 325 (NK1R Δ 325). Full-length and truncated (Δ 325) human NK1R desensitize similarly, using two independent readouts of receptor signaling, intracellular IP₃ accumulation and subcellular redistribution of fluorescently tagged PKC- β II in live cells. However, truncated and full-length NK1R differ, in GRK-catalyzed phosphorylation and in their ability to form endocytic vesicles with two distinct β -arrestins, β -arrestin 1 and 2. Truncated NK1R, unlike full-length NK1R, does not undergo phosphorylation following exposure to SP. Also, full-length NK1R forms endocytic vesicles equally well with either β -arrestin 1 or β -arrestin 2, while truncated NK1R does not form any endocytic vesicles with β -arrestin 1 and forms fewer vesicles with β -arrestin 2. These data indicate that full-length and truncated NK1R are likely to behave differently during endocytosis and receptor recycling.

The Role of NK1R in Human Disease

While SP and NK1R have been studied for several decades, renewed interest in NK1R biology was generated following the report in 1998 that NK1R antagonists have antidepressant activity. This discovery generated so much enthusiasm that a commentary titled 'Reward for persistence in substance P research' by Claes Wahlestedt appeared in *Science* along with a timeline highlighting important events throughout the history of SP research (Figure 4). The first NK1R antagonist was introduced into clinical medicine as an antiemetic, and active research continues to investigate the role of NK1R in the pathophysiology of several diseases, including emesis, depression, and glioblastoma. Recent preliminary research has also implicated NK1R in HIV, fibromyalgia, and lung inflammation.

NK1R in Emesis

An important role for NK1R in emesis is indicated by clinical trials showing that the nonpeptide NK1R antagonist, MK-869 (also called aprepitant), is effective against prevention of both chemotherapy-induced nausea and vomiting (CINV) and post-operative nausea and vomiting (PONV). NK1R influences emesis through its role as a key regulator of the emetic reflex arc in the brainstem. Clinical trial investigators noted that during the acute phase of CINV (the first 24 h), aprepitant was only effective in 37% of patients, while the standard therapy, ondansetron, was effective in 57% of patients. By contrast, during the delayed phase of CINV (the succeeding 6 days)

aprepitant was effective in 72% of patients while ondansetron was effective in only 7% of patients. A later clinical trial compared standard therapy of ondansetron and dexamethasone with standard therapy plus aprepitant. This study found statistically significant improvement in percentages of patients achieving complete response, as indicated by no emesis or use of rescue therapy, in the overall study period (72.7% vs. 52.3%), acute phase (89.2% vs. 78.1%), and delayed phase (75.4% vs. 55.8%). Taken together, these two studies suggest that acute and delayed phase nausea may involve different molecular mechanisms and that SP is primarily active in the delayed phase of CINV.

Another clinical trial tested a triple combination of aprepitant, granisetron, and dexamethasone for suppression of CINV. In this trial, 87% of patients receiving the triple combination reported that nausea did not affect their ability to perform daily functions, in comparison to 67% of patients receiving only granisetron and dexamethasone. In 2003, aprepitant received Food and Drug Administration (FDA) approval for use in combination with other antiemetic drugs to prevent CINV, which is a particular problem in high-dose cisplatin therapy, followed by approval for combination therapy to prevent PONV in 2006. This result points to NK1R as a promising target protein for future efforts to understand and control nausea. Indeed, several NK1R antagonists are currently in development for treating CINV, including casopitant, which has completed phase 3 clinical trials.

NK1R in Depression and Affective Disorders

Substantial research implicates SP in the regulation of depression, anxiety, stress, and other affective disorders, and the distribution of SP and NK1R in the brain is consistent with this role. For instance, SP is the predominant tachykinin in human brain, and the expression of SP is particularly concentrated in areas of the brain that control either affective behavior or stress responses, such as the hypothalamus, amygdala, habenula, periaqueductal gray, and dorsal raphe nucleus. Likewise, NK1R is the most highly expressed tachykinin receptor in the brain and is also concentrated in areas that are important for affective behavior.

Initial evidence of a role for SP in depression was found in a randomized, double-blind, placebo-controlled study of patients with moderate to severe major depression, which showed that the NK1R antagonist, aprepitant, has antidepressant activity equivalent to paroxetine, a current standard therapy. However, pursuant phase 3 trials were unable to confirm early efficacy

signals and do not support further development of aprepitant in patients with major depression or high anxiety. Regardless, the improved tolerability profile expected from NK1R antagonists continues to drive research in this therapeutic area, given the medication adherence and discontinuation issues caused by significant side effects associated with standard of care antidepressant treatments. Specifically, a second NK1R antagonist, L759274, has shown positive results in clinical trials, further supporting a role for NK1R in depression. Future efforts may study the therapeutic potential of dual antagonists targeting both NK1R and NK2R for more complete blockade of SP. Furthermore, attenuation of stress-activated pathways by NK1R antagonists in preclinical models suggests therapeutic potential in stress-related disorders.

NK1R in Glioblastomas

Glioblastomas, classified as grade IV astrocytomas, are among the most aggressive and frequently occurring primary brain tumors in adults. Patients with glioblastomas have an extremely poor prognosis: with a 5-year survival rate of 1%, the currently available treatments of surgery, radiation therapy, and chemotherapy are inadequate. Current research focuses on understanding glioblastoma biology and identifying molecular targets for blocking tumor growth. SP has been observed to have a growth-promoting effect in a variety of cell types, and its role in glioblastoma growth is currently being studied. One study noted NK1R expression in 9 out of 12 astrocytomas, and 10 out of 10 glioblastomas. Furthermore, the density of NK1R correlates with the degree of malignancy, with glioblastomas expressing more receptors than astrocytomas. At the molecular level, NK1R stimulation in U373 MG human glioblastoma cells increases mitogenesis, cell proliferation, and release of interleukin-6 (IL-6). NK1R-dependent release of IL-6 is noteworthy because IL-6 has been implicated in the progression of gliomas. Consistent with an important role in glioblastoma biology, NK1R antagonists are reported to inhibit the growth of glioblastomas in nude mice. These findings, along with results from our laboratory indicating the presence of a constitutively active form of NK1R and NK1R-mediated apoptosis of glioblastoma cells, suggest a therapeutic potential for NK1R antagonists in glioblastoma management.

A diagnostic or therapeutic role has been implicated for NK1R in other carcinomas as well, including breast, pancreatic,

and lung. Preclinical studies suggest that NK1R overexpression in these tissues may indicate and facilitate tumor metastasis. Thus, the potential for the clinical introduction of NK1R antagonists to cancer treatment will remain an active area of research.

Glossary

Taste quality The perceptual quality attributed to a taste stimulus, such as salty, sour, sweet, bitter, or umami.

Taste receptor cell Elongate, spindle-shaped cell in taste buds that expresses taste receptors and/or transduction components.

Taste receptor Membrane protein that interacts with taste stimuli, leading to activation of a transduction cascade, receptor cell depolarization, and transmitter release onto afferent nerve fibers.

Transduction The process, often involving a biochemical cascade, by which one type of signal (e.g., a taste stimulus) is converted to another type (e.g., depolarization of the TRC).

Taste Receptor Cells

The initial events in taste processing occur in taste buds, structures found in the epithelia of the tongue, palate, larynx, and epiglottis of mammals, which contain approximately 50–100 cells of neuroepithelial origin (**Figure 1**). Taste buds contain morphologically distinct cell types, including elongate, spindle-shaped cells that express a variety of identified transduction-related proteins (including taste receptors) and therefore likely function as taste receptor cells (TRCs). TRCs possess apical processes with microvilli that protrude into the oral cavity and interact with taste stimuli. These microvilli contain taste receptors and taste-responsive ion channels. Tight junctions between the cells in a taste bud restrict the access of most stimuli to the apical membranes of the cells. TRCs synapse with afferent special sensory fibers from one of three cranial nerves (VII, IX, and X), and taste information is subsequently relayed through brainstem nuclei to forebrain taste areas or to local circuits controlling oromotor reflexes.

Multiple signaling cascades in TRCs have been described, and there are fundamental differences in the transduction pathways associated with each stimulus quality. For example, salt and acid stimuli directly permeate or activate apical ion channels, leading to TRC depolarization, while umami-, sweet-, and bitter-tasting stimuli are thought to predominantly activate taste receptors that can initiate an intracellular cascade of signaling molecules. Receptors for bitter, sweet, umami, salty, and sour taste appear to be expressed in nonoverlapping populations of TRCs. Stimulus-dependent release of adenosine triphosphate (ATP) from at least some TRCs leads to direct activation of purinergic receptors present on afferent nerve fibers, and may be a primary mechanism by which taste information is transmitted from taste bud to sensory nerves. Recent findings also support the potential for information processing within taste buds via several paracrine and autocrine signaling mechanisms.

G-Protein-Coupled Taste Receptors

The largest gene superfamily in the mammalian genome encodes the group of proteins known as G-protein-coupled

receptors (GPCRs). GPCRs play critical roles in a variety of cellular functions, including neurotransmitter and hormonal signaling and the detection of sensory stimuli. Although they are quite diverse in amino acid sequence, all GPCRs share common structural and functional features. Their most striking structural motif is their seven helical transmembrane domains; that is, the GPCR polypeptide passes seven times through the plasma membrane, leaving an extracellular amino terminus and intracellular carboxy terminus. GPCRs also share a common signaling mechanism, as is evidenced by their name: activation of a GPCR by its ligand initiates an intracellular signaling cascade via the stimulation of an associated heterotrimeric guanosine triphosphate (GTP)-binding protein (G protein). Most chemosensory receptors are GPCRs, including odorant receptors, vomeronasal receptors, and taste receptors. In the taste system, two families of GPCR-type taste receptors (T1Rs and T2Rs) detect sweet-, umami-, and bitter-tasting stimuli.

T1R Receptors

Sweet and umami are appetitive taste qualities that drive intake of food. Diverse compounds evoke sweet taste, including some sugars, D-amino acids and proteins, as well as numerous artificial sweeteners. By contrast, umami taste is evoked by a small number of L-amino acids and 5'-ribonucleotides found in meats and other foods. The receptors for sweet and umami taste are called T1Rs, and function as heterodimeric complexes. Specifically, T1R1 and T1R3 together form a functional receptor for umami-tasting stimuli (e.g., L-amino acids) but are unresponsive to sweet-tasting stimuli, while T1R2 and T1R3 together comprise a receptor for sugars, artificial sweeteners, sweet proteins, and D-amino acids. The native T1R1 and T1R2 subunits are co-expressed with T1R3 in different subsets of TRCs. Thus, T1R3 is a common subunit for receptors with different ligand specificities. Furthermore, these ligand specificities largely depend on the whether the receptor complex contains T1R1 or T1R2.

T1R receptors are class C GPCRs, a group that also includes receptors for glutamate, γ -amino butyric acid and calcium. Class C GPCRs exhibit a large extracellular domain at the amino terminus that comprises approximately 50% of the protein length, a membrane-spanning domain that includes

Figure 1 Taste receptor cells. (a) Taste buds are specialized sensory structures located in the epithelia of the mammalian tongue (arrows indicate approximate locations of taste buds), as well as palate, larynx, and epiglottis (not shown). (b) Schematic of a taste bud. Taste buds contain 50–100 cells of morphologically distinct types, including elongate, spindle-shaped cells (arrow) that express taste receptors.

Figure 2 The proposed structures of taste receptor proteins. Amino acid and sweet- and bitter-tasting stimuli are detected by GPCR-type taste receptors. Salt and acid stimuli activate TRCs through a GPCR-independent mechanism; they directly permeate or modulate ion channels, some of which may belong to the DEG/ENaC family.

seven transmembrane helices, and a linker domain joining the two (Figure 2). The amino-terminal domain contains the principal site of ligand binding in class C GPCRs. In the case of T1Rs, this domain contains the binding site(s) for natural sugars, amino acids, and some artificial sweeteners (e.g., sucralose and aspartame). However, T1Rs also contain several other binding sites (e.g., in the transmembrane domain of T1R3) that can bind selected compounds such as the artificial sweetener cyclamate and the sweet taste inhibitor lactisole.

In the gustatory system, T1Rs are found on subsets of taste cells that are linked to a single perceptual quality. For example, T1R2 and T1R3 are co-expressed only in taste cells that elicit a sensation of sweetness, while T1R1 and T1R3 are expressed together in a separate TRC subpopulation that elicit an umami sensation when activated. However, it is now clear that T1Rs (and T2Rs; see below) are found in numerous tissues

outside the gustatory system, including the stomach, intestine, pancreas, and brain. In the gastrointestinal system, T1Rs and associated signaling molecules have been implicated in the regulation of glucose assimilation and glucose-dependent hormonal secretion from enteroendocrine cells. Thus, it appears that mammals use T1Rs as sugar and amino acid sensors throughout the body.

T2R Receptors

A second class of GPCRs, the T2Rs, also function as taste receptors. T2Rs respond to a large number of bitter-tasting compounds. Mammals have a large number of T2R genes (humans have approximately 25 functional T2R genes as well as several apparent pseudogenes). T2Rs loosely resemble class A GPCRs (the same class as mammalian odorant receptors and the light-sensitive receptor rhodopsin), which are characterized by a short amino terminus (Figure 2). Many class A GPCRs bind their ligands within a pocket defined by several of the transmembrane helices and/or the nearby extracellular loops. It has been proposed that both the transmembrane helices and extracellular loops are involved in ligand binding.

Ligands for most human T2Rs have been identified. Individual T2Rs each recognize multiple bitter-tasting stimuli, although the degree of ligand selectivity of each T2R can vary considerably. For example, hT2R14 responds to a structurally diverse set of stimuli, whereas just two agonists activate the recently deorphanized receptor hT2R50. Some T2R receptors, such as hT2R38 and hT2R16, appear to recognize common structural elements in chemically related compounds. Finally, specific compounds have been shown to activate multiple receptors, although sometimes with different efficacies.

The bitter receptor gene family in vertebrates comprises a relatively conserved family size (~15–37 functional genes) with multiple orthologs among mammalian species. This gene family also exhibits a fairly high rate of nonsynonymous mutations, especially in the portions of the genes that code for extracellular domains. It is thought that haplotype frequencies of T2R genes are strongly affected by natural selection, and are moreover associated with factors such as dietary preference and eating behavior.

T2Rs, like T1Rs, are also found in various tissues where they may act as sensors of diverse chemicals. For example, both bitter-tasting compounds and substances produced by pathogenic bacteria can activate T2R-expressing sensory cells in the nasal cavity and promote respiratory reflexes. However, it remains unclear if T2Rs mediate aversive signals in all tissues. Indeed, T2Rs are co-expressed with T1Rs in gut enteroendocrine cells, and may promote similar hormonal responses.

Ion Channels as Taste Receptors

Taste cells rely on the actions of a variety of ion channels to support stimulus-induced changes in membrane polarization and the synaptic release of neurotransmitter. However, several ion-channel species can be thought of as receptors for taste stimuli: the channels interact directly with the taste stimulus and participate in the initial stage of taste transduction. Such channels play a central role in the detection of

salty- and sour-tasting stimuli. In rodents, a large portion of salt taste is dependent on the influx of Na^+ through the epithelial sodium channel ENaC. The ENaCs, members of the degenerin (DEG)/ENaC superfamily of ion channels, are strongly Na^+ selective. DEG/ENaC family members display a common topology: they have two transmembrane domains, a large extracellular loop and a small pore-forming loop (Figure 2). They function as hetero-oligomeric complexes. Data supporting a role for ENaCs in sodium taste are compelling. However, ENaC-independent mechanisms are also implicated in mammalian salt taste, especially for nonsodium salts such as KCl.

Sour (acid) taste stimuli (i.e., H^+) have been proposed to depolarize TRCs in vertebrates via several different mechanisms, including by activating cation channels or by directly permeating ion channels. PKD2L1, a polycystic-kidney-disease-like ion channel expressed in sour-sensitive TRCs has been suggested as a candidate sour taste receptor. However, evidence supporting a primary role in sour taste remains equivocal. Other candidates for sour taste receptors include members of a family of proton-gated ion channels related to the superfamily of DEG/ENaC sodium channels family, the acid-sensing ion channels (ASICs).

Transduction Cascades

The mechanisms of taste transduction are still not fully understood. The G-protein subunit α -gustducin is implicated in sweet-, umami-, and bitter-taste transduction, although other
